resulting hydroxylamine to the oxoammonium salt *in situ*. In the best cases, the stoichiometric oxidant is cheap (such as bleach), or even cleaner, such as O_2 or electrochemical anodic oxidation. Conditions employing a stoichiometric cooxidant are generally milder than acid-catalyzed disproportionation. Since reactions are usually conducted under basic conditions, very high selectivity for primary alcohols in the presence of secondary alcohols is observed. Secondary alcohols can also be oxidized in good yields, but they need substantially longer reaction times. Despite the diversity of nitroxide radicals, TEMPO is frequently used, due to its cost and accessibility.

On the basis of the reversible acid-catalyzed disproportionation of nitroxides, the general mechanisms of catalytic oxidation are described by two different scenarios, dictated as a function of pH .^{73,119} Under highly acidic conditions ($pH < 2$) (Scheme 42), two nitroxides disproportionate to form one hydroxylamine and one oxoammonium salt. The latter oxidizes the alcohol; in doing so, it is reduced to the hydroxylamine. One-electron oxidation by the primary oxidant regenerates the nitroxide, which returns to the catalytic cycle.

Scheme 42 Catalytic cycle of nitroxide-mediated alcohol oxidation under strongly acidic conditions.

Scheme 43 Catalytic cycle of nitroxide-mediated alcohol oxidation under weakly acidic and basic conditions.

Alternatively, at higher pH (Scheme 43), the primary oxidant converts the nitroxide to the oxoammonium species, which is consumed by alcohol oxidation, reforming the hydroxylamine. The hydroxylamine can also react with an oxoammonium ion to regenerate two nitroxide radicals in a synproportionation reaction.

From both an economic and an environmental viewpoint, the use of “green” oxidants such as oxygen or hydrogen peroxide is ideal. The use of oxygen as a primary oxidant in conjunction with TEMPO and a transition metal catalyst (aerobic oxidation) has been investigated by a number of researchers (*vide supra*). Generally, the alcohol is oxidized by an oxoammonium cation, generating TEMPOH as a byproduct. The metal catalyst oxidizes the hydroxylamine to TEMPO, which is further oxidized by a second equivalent of metal

catalyst back to the key oxoammonium salt. The reduced form of metal catalyst is reoxidized by oxygen as the primary oxidant. These conditions work with a broad range of alcohols. For example, an oxoammonium cation is formed by aerobic oxidation of TEMPO with the heteropoly acid H₅PV₂Mo₁₀O₄₀¹²⁰ or with ceric ammonium nitrate (CAN)¹²¹ (Scheme 44).

Alternatively, the oxoammonium salt can be generated via disproportionation of TEMPO in acetic acid under Minisci conditions,^{98,122} in which Mn(II)–Co(II) or Mn(II)–Cu(II) nitrates are used to regenerate TEMPO from TEMPOH in the presence of oxygen. An easily recyclable reagent is the tetranitroxide derived from the commercially available hindered amine “CHIMASSORB® 966,” which can be recovered by precipitation from organic solvents.¹²³

The use of multicopper laccase enzymes has attracted much attention as a catalytic metal oxidant. These oxidase enzymes contain four copper centers per protein molecule. Laccase enzymes are secreted by white rot fungi to delignificate the lignocelluloses found in wood.¹²⁴ Galli and coworkers have reported a laccase/TEMPO system that catalyzes the oxidation of benzylic, allylic, and aliphatic alcohols as well as benzylic amines.¹²⁵ However, 20–30 mol% of TEMPO is required, and this system is most effective with benzylic and allylic substrates. TEMPO outperforms other nitroxides examined in this oxidation.^{126,127} The mechanistic details of this oxidation process are not completely clear, but it is assumed that electron transfer occurs from TEMPO to a Cu(II) in the laccase, forming an oxoammonium cation.^{128–130} A kinetic isotope effect of $k_H/k_D = 2.05$ is consistent with an oxoammonium pathway.¹²⁷ Air is necessary to regenerate the Cu(II) species. The mechanistic pathway of the laccase/TEMPO system is different from other Cu/TEMPO systems (*vide infra*) due to the much higher redox potential of Cu(II) in laccase. It has been shown that laccase/TEMPO can catalyze the aerobic oxidation of primary alcohols in carbohydrates to form polycarboxylic acids.¹¹⁹ The biodegradable carboxystarch product is an excellent water absorbent, with potential applications for use in diapers. However, obstacles toward large-scale manufacture include the high cost and the instability of the enzyme.

Anelli *et al.*^{131,132} have developed a popular protocol that utilizes household bleach (sodium

Scheme 44 Catalytic cycle of CAN-mediated aerobic oxidation of alcohols.

Scheme 45 Anelli oxidation of alcohols with TEMPO/NaOCl/KBr.

hypochlorite) as the stoichiometric oxidant and requires only 1 mol% of the nitroxide. This oxidation uses mild biphasic conditions ($\text{CH}_2\text{Cl}_2/\text{H}_2\text{O}$, pH 8.6–9.5); addition of bromide ion as a cocatalyst provides aldehydes in high yields with reaction times of only minutes. Bromide is oxidized by bleach to form hypobromite (a more reactive oxidant than hypochlorite) for regeneration of the oxoammonium salt (Scheme 45). Oxidation of secondary alcohols requires slightly longer reaction times. Overoxidation of aldehydes to carboxylic acids resulted on addition of a phase transfer reagent. Carboxylic acids were obtained cleanly using sodium chlorite (NaClO_2) as the terminal oxidant with catalytic amounts of TEMPO and bleach in aqueous acetonitrile (Merck's method).^{112,133,134} The oxoammonium salt, resulting from the combination of TEMPO and bleach, oxidizes the alcohol to the corresponding aldehyde. The hydrated hemiacetal then reacts with sodium chlorite to form the carboxylic

acid. Anelli conditions have been utilized for the selective oxidation of monosaccharides^{135–137} (Scheme 46), disaccharides,¹³⁸ oligosaccharides,¹³⁹ and polysaccharides^{119,140–144} to their corresponding carboxylic acids. These reaction conditions are mild enough that epimerization does not occur with optically pure α -amino and α -hydroxy aldehydes (Scheme 46).^{145,146} Recently, TEMPO-catalyzed oxidation with bleach has been performed in a spinning tube-in-tube reactor,¹⁴⁷ eliminating the need for slow addition of bleach to control the exothermic reaction. The rapid mixing and efficient heat transfer resulted in increased yields and enhanced reaction rates.

Although the Anelli protocol is widely utilized, it is not waste-free: the use of bleach produces 1 equiv of sodium chloride for every molecule of alcohol oxidized. Chlorinated byproducts are sometimes formed. Alternative cooxidants include iodine-based oxidants, such as [bis(acetoxy)iodo]benzene ($\text{PhI}(\text{OAc})_2$, BAIB),¹⁴⁸ iodine (I_2),¹⁴⁹ periodic acid (H_5IO_6),¹⁵⁰ iodine pentoxide (I_2O_5),¹⁵¹ sodium periodate (NaIO_4),¹⁵² iodobenzene dichloride (PhICl_2),¹⁵³ and 1-chloro-1,2-benziodoxol-3(1*H*)-one.¹⁵⁴ Other oxidants examined include *N*-chlorosuccinimide,¹⁵⁵ Oxone®,¹⁵⁶ hydrogen peroxide,¹⁵⁷ sodium bromite (NaBrO_2),¹⁵⁸ and pyridine/ HBr_3 .^{159,160} Trichloroisocyanuric acid (TCCA) can also be used as a hypochlorite equivalent.^{161,162} Margarita's TEMPO-mediated alcohol oxidation protocol using BAIB as the terminal oxidant¹⁴⁸ is particularly good at avoiding epimerization with sensitive substrates. Thus, it

Scheme 46 Anelli oxidation of methyl α -D-galactopyranoside¹³⁷ and *N*-tosyl- α -amino alcohol.¹⁴⁶

has become very popular, as exemplified by its use in the total syntheses of natural products such as pteridic acid A,¹⁶³ guanacastepene A,¹⁶⁴ and bengamide E.¹⁶⁵ In the case of bengamide E, an antitumor natural product of marine origin, oxidation of an alcohol to the carboxylic acid was successful in the presence of water (Scheme 47).

Both the Anelli¹³² and Margarita¹⁶⁶ conditions oxidize 1,4- and 1,5-diols to the corresponding γ - and δ -lactones, respectively, via a cyclic hemiacetal

intermediate. Both conditions also exhibit high chemoselectivity for oxidation of primary alcohols. Aerobic oxidation of benzylic alcohols has been demonstrated with catalytic amounts of TEMPO/BAIB/ KNO_2 under solvent-free conditions.¹⁶⁷ Immobilization of BAIB on polystyrene (PS) allows for the recycling of this catalyst. An oxidative rearrangement of tertiary allylic alcohols with catalytic TEMPO failed using bleach, BAIB, or Oxone[®] as the stoichiometric oxidant. However, it worked well when NaIO_4 on silica gel¹⁶⁸ or PhIO in conjunction with a Lewis acid^{169,170} were employed as terminal oxidants. TEMPO and related derivatives are more effective catalysts than other nitroxides.¹⁷¹ Recently, unhindered 1-methyl-azaadamantane *N*-oxyl (1-Me AZADO)^{77,172} and several azabicyclo *N*-oxyls,^{173,174} such as 9-azabicyclo[3.3.1]nonane-*N*-oxyl (ABNO)¹⁷⁴ (Figure 1), have been shown to exhibit even greater activity than TEMPO under Anelli, Margarita, and electrochemical oxidation conditions.

Hu and coworkers reported the first transition metal-free aerobic alcohol oxidations with catalytic TEMPO using $\text{Br}_2/\text{NaNO}_2/\text{O}_2$.¹⁷⁵ They demonstrated that HCl ¹⁷⁶ or 1,3-dibromo-5,5-dimethylhydantoin¹⁷⁷ could serve the same function as Br_2 . The nitric oxide precursor NaNO_2 can also be replaced by *tert*-butyl nitrite.^{178,179} Recently, Yang and coworkers have shown that both NO and Br^- can be generated *in situ* by reaction of $\text{NH}_2\text{OH}\cdot\text{HCl}$ and KBrO_3 .¹⁸⁰ The proposed mechanism for alcohol oxidations using catalytic amounts of TEMPO/ NaNO_2/HCl

Figure 2 Examples of silica- and polymer-supported TEMPO reagents.

and air as the ultimate oxidant is described in Scheme 48. The alcohol is oxidized by the oxoammonium salt, which is regenerated by oxidation of TEMPOH with NOCl. NOCl is formed by reaction of HCl and NO₂⁻, which is generated by air oxidation of NO. Water is a byproduct of this reaction cycle.

Although only catalytic amounts (often 1 mol%) of nitroxide are commonly used in alcohol oxidations, the ability to efficiently isolate and recycle the catalyst is also important. Hence, many groups have designed variants on immobilized nitroxides anchored to solid supports, such as silica^{181–183} or mesoporous silica MCM-41.¹⁸⁴ Other strategies include entrapment in a silica sol–gel^{185–187} or coupling the nitroxide to functionalized polymers.^{188,189} Silica-supported TEMPO catalysts have several advantages: they are easily

isolated by filtration, a high catalyst activity can be realized due to the high surface area, the nitroxides can be cleanly regenerated electrochemically, and some are commercially available (e.g., SiliaCat^{®190} (Figure 2) and FibreCat^{®191}). The heterogeneous catalysts are often less active than the homogeneous catalysts.¹⁹² Most of the TEMPO–polymer conjugates are soluble in selected organic solvents; the catalyst is recovered by precipitation induced by changing the solvent system¹⁹³ or by dialysis.¹⁹⁴ PEG-supported TEMPO (Figure 2)¹⁹⁵ is the most popular homogeneous catalyst for use under Anelli,^{189,196–198} Minisci,¹⁹⁹ and aerobic copper-mediated conditions.^{195,200} The recyclable polyamine-immobilized piperidinyl oxyl (PIPO)^{192,201} (Figure 2) prepared from the commercially available antioxidant and light stabilizer CHIMASSORB[®] 944, in combination with bleach

Scheme 49 Oxidation of cholesterol by a polystyrene oxoammonium resin.

exhibited higher activity (per nitroxyl group) than TEMPO, silica-, and MCM-41-supported TEMPO.

There are several TEMPO–polymer conjugates that behave as insoluble heterogeneous catalysts, such as polystyrene PS-based TEMPO^{188,194,202,203} and TEMPO-functionalized PS encapsulated in polyurea microcapsules.²⁰⁴ Recently, Studer and coworkers reported TEMPO–poly(amidoamine) dendrimer conjugates coated inside polyparaxylylene nanotubes²⁰⁵ for benzylic alcohol oxidations under Anelli conditions. As shown in Scheme 49, cholesterol was oxidized by a preformed oxoammonium PS resin to form an enolizable ketone intermediate, which was further converted to the dione.¹⁰⁸ Tanaka and coworkers have regenerated polymeric oxoammonium salts by electrochemistry.²⁰⁶ Immobilized cooxidants such as poly[4-(diacetoxyiodo)styrene],^{207–209} polymer-supported bis-acetoxylbromate(I) anion,^{210,211} and polymer-supported hypochlorite resins^{212,213} have been developed.

Instead of attaching the nitroxide to a solid support, monomeric TEMPO tethered to a charged imidazolium species (Figure 3)²¹⁴ can be isolated by extraction into an ionic liquid, leaving the oxidized product in the organic layer.^{215,216} Imidazolium salts have also been tethered to 2,2'-bipyridine (bipy) ligands for use in TEMPO/Cu oxidations.²¹⁷ The nitroxide *N*-acetyl-4-amino-TEMPO was found to be soluble in an ionic liquid, but

Figure 3 Examples of TEMPO derivatives bearing imidazolium salt and fluororous tags.

not in ether, allowing it to be recycled thrice without loss of activity.²¹⁸ Perfluoroalkyl chains impart solubility in fluororous solvents (Figure 3).²¹⁹ Several fluororous-tagged TEMPO derivatives have been applied successfully under Anelli,^{219–222} Margarita,²¹⁹ and Minisci^{221,223} oxidation conditions. This strategy has also been used to append perfluoroalkyl chains on 2,2'-bipy ligands for TEMPO/Cu-mediated alcohol oxidations, allowing the Cu–ligand complexes to be reused several times.^{223–226} Recently, TEMPO was immobilized on saponite, allowing isolation of the nitroxide by filtration,²²⁷ and on graphene-coated cobalt nanoparticles,²²⁸ which can be separated from solution by magnetic decantation.

As an alternative to chemical oxidants, electrochemistry has also been utilized to reoxidize nitroxides in alcohol oxidations. Cyclic voltammetry has been used to measure the formation of oxoammonium salts from nitroxides: the lower the oxidation potential of the nitroxide, the more effective the nitroxide is at mediating alcohol oxidation.¹⁷¹ Oxidation potentials are also a function of solvent polarity; polar solvents enhance the oxidation efficiency.²²⁹ Electrooxidations have been conducted in dichloromethane, acetonitrile, biphasic medium, or water in a divided cell^{230,231} as well as in undivided cells.²³² Ionic, water soluble,^{233,234} or polymer immobilized^{206,235,236} nitroxides have been used in electrooxidation of alcohols (see

Scheme 50 Mechanism for the visible light-induced aerobic oxidation of primary alcohols in a coupled photocatalytic dye-sensitized TiO_2 /TEMPO system.

Electrochemically Initiated Radical Reactions).

Nitroxides have been immobilized on the electrodes to simplify the work-up.^{237–239} The popular nitroxide SG1, commercially available from Arkema, was successfully used in electrooxidation of 4-methylbenzyl alcohol, which showed smoother electron transfer on the electrode compared to TEMPO.²⁴⁰ TEMPO electrooxidation has been performed in an ionic liquid.²⁴¹ Schafer and Bashiardes have demonstrated the nitroxide-catalyzed oxidation of mono-, di-, oligo-, and polysaccharides electrochemically.^{33,110,232,242}

Recently, an interesting method to regenerate an oxoammonium cation from the nitroxide using visible light has been reported (Scheme 50).²⁴³ This system consists of the dye Alizarin as a sensitizer, TiO_2 as an electron acceptor, and TEMPO as a cocatalyst in benzotrifluoride as solvent. Under irradiation with visible light ($\lambda > 450 \text{ nm}$), an electron from the excited state of the dye is transferred to the conduction band of TiO_2 ; the dye radical oxidizes TEMPO to the oxoammonium cation. After alcohol oxidations, the resulting TEMPO is then regenerated by either oxygen or the dye radical cation. In a similar system, porphyrin was utilized as the photosensitizer and quinone as the electron acceptor.²⁴⁴

5.2.2 Kinetic Resolution and Desymmetrization

Optically pure nitroxides¹⁰ have been used as oxidants to carry out kinetic resolution of racemic

substrates and desymmetrization of *meso* substrates. The selectivity value S is often used to combine both %ee (enantiomeric excess) and conversion into a measure of overall effectiveness in kinetic resolution. Bobbitt and coworkers reported the first examples of kinetic resolution of alcohols with a chiral nitroxide using 4-NHAc SPIROXYL,^{245,246} including the asymmetric lactonization of diols.^{245,247} Using an axially chiral nitroxide²⁴⁸ or nitroxyl peptide (TOAC)²⁴⁹ under Anelli conditions, moderate selectivities in the kinetic resolution of secondary alcohols was achieved ($S = 3.9\text{--}7.1$ and 2.3 , respectively). Electrochemical oxidation with the axially chiral nitroxide provided S values as high as 20 .²⁵⁰ Several chiral bridgehead nitroxides were examined; however, most of them were unstable under oxidation, resulting in poor S -values.²⁵¹ Recently, excellent enantioselectivities (S values up to 82) using the chiral azaadamantane nitroxide AZADO in combination with TCCA has been reported (Scheme 51).^{252,253} (–)-Sparteine has been used as a chiral base with TEMPO-modified electrodes^{247,254,255} and as

Scheme 51 Enantioselective organocatalytic oxidative kinetic resolution of secondary alcohols using optical AZADO.

a ligand with copper²⁴² in enantioselective oxidations. A chiral copper complex, prepared from $\text{Cu}(\text{OTf})_2$ and (*R*)-BINAM was used with TEMPO in the oxidative kinetic resolution of racemic amino alcohols,²⁵⁶ benzylic alcohols, and benzoin.²⁵⁷ Kinetic resolution of secondary amines²⁵⁸ and oxazolidines²⁵⁹ have also been reported. Optically active acyl and diacyl (phthalimido) nitroxides have been used in both oxidative kinetic resolution and desymmetrization^{260,261}; however, the mechanism does not involve an oxoammonium salt, but rather hydrogen abstraction (*vide infra*).

5.2.3 Other Oxidations Mediated by Oxoammonium Salts

A variety of sulfides can be oxidized selectively to sulfoxides in nitroxide-mediated reactions under Anelli^{262–265} or copper-mediated²⁶⁶ conditions. For example, TEMPO-linked Fe- and Mn-metalloporphyrins were used as a catalyst to oxidize sulfides to the corresponding sulfoxides without overoxidation to the sulfone.²⁶⁵ The glycosyl sulfide in Scheme 52 was chemoselectively oxidized in the presence of two hydroxyl groups under Anelli conditions. The electrochemical oxidation of thiols to disulfides has been accomplished with a TEMPO-modified electrode.²⁶⁷

Trisubstituted alkenes can undergo allylic oxidation with oxoammonium salts to form alkoxyamines: Bobbitt and coworkers have suggested an ene-type mechanism.²⁶⁸ Similar examples include the allylic oxidation of dienes, activated alkenes,²⁶⁹ and tetrahydrocarbazole²⁷⁰ to form the corresponding conjugated ketones in excellent yields. For example, 1,2,3,4-tetrahydrocarbazole (Scheme 53) was oxidized to the ketone in 71% yield. The proposed mechanism involves nucleophilic attack by the indole on the oxoammonium salt, followed by intramolecular elimination to give the unsaturated iminium cation. Conjugate addition of water forms the 4-hydroxytetrahydrocarbazole, which is subsequently oxidized to the ketone product.

Oxidative cleavage of benzyl alkyl ethers occurs on treatment with oxoammonium salts bearing nonnucleophilic counterions such as BF_4^- (Scheme 54). The mechanism occurs via benzylic hydride transfer to the electrophilic oxygen of the oxoammonium salt; hydrolysis of

Scheme 52 Oxidation of a glycosyl sulfide to the corresponding sulfoxide with a TEMPO-linked Mn-metalloporphyrin under Anelli conditions.

the oxygen-stabilized benzylic cation forms an aromatic aldehyde and an aliphatic alcohol.¹⁰⁵ The aliphatic alcohol is further oxidized to the corresponding ketone or carboxylic acid. In contrast, using a nucleophilic bromide counterion to the oxoammonium cation, anhydrous conditions result in the formation of an aromatic aldehyde and an alkyl bromide.^{271,272}

Baeyer–Villiger reactions of α -hydroxy ketones can be carried out by nitroxides plus an oxidant, such as bleach.^{273–275} In the first step, the α -hydroxy ketone is oxidized by the oxoammonium salt to the corresponding α -diketone, which undergoes further oxidation to form the anhydride. The mechanism for the oxidative ring enlargement is not clear, but may occur by nucleophilic addition of the hydroxyamine anion to one of the carbonyls, followed by ring expansion with loss of the hindered aminyl anion. For example, peptides can be prepared from β -lactams via nitroxide-mediated Baeyer–Villiger reaction under Anelli conditions, followed by nucleophilic amidolysis with an amino acid (Scheme 55).²⁷⁵

Scheme 53 Allylic oxidation of 1,2,3,4-tetrahydrocarbazole to 4-keto-1,2,3,4-tetrahydrocarbazole by 2 equiv of an oxoammonium salt.

Scheme 54 Oxidative cleavage of a benzylic ether using a typical oxoammonium salt.

5.3 Oxidations via Hydrogen Abstraction

5.3.1 Copper-, Ruthenium-, and Iron-Catalyzed Aerobic Oxidations

A number of reports utilize copper, ruthenium, or iron with a nitroxide and oxygen to oxidize alcohols to carbonyl compounds. This literature has been reviewed by Sheldon and Arends^{7,8} and Sheldon *et al.*⁷⁵ Copper cocatalysts are the most extensively investigated among the transition metals in these aerobic nitroxide oxidations. Semmelhack *et al.* proposed that benzylic and allylic alcohols were oxidized by CuCl/TEMPO via the oxoammonium salt.^{106,276} Evidence against this pathway includes the lower reaction rates of aliphatic and alicyclic alcohols compared to benzylic and allylic substrates. This chemoselectivity is inconsistent with a mechanism involving an oxoammonium cation,

whose reactivity is broad in scope. Stoichiometric experiments under anaerobic conditions support the formation of an electrophilic Cu/TEMPO complex rather than an oxoammonium species.²⁷⁷ Additional evidence for an alternative reaction pathway includes kinetic isotope effects and Hammett correlation studies. The primary kinetic isotope effect for the CuCl/TEMPO catalyzed aerobic oxidation ($k_H/k_D = 5.42$) compares well with those observed with other metal-centered dehydrogenations of alcohols, such as a Ru/TEMPO system,²⁷⁸ galactose oxidase,²⁷⁹ and a biomimetic copper complex.²⁸⁰ In contrast, the kinetic isotope effects observed in stoichiometric oxoammonium cation oxidations are much smaller ($k_H/k_D = 1.7\text{--}2.3$).¹⁰⁶ The Hammett ρ value for the CuCl/TEMPO system also compares well with that of a galactose oxidase mimic. Sheldon and coworkers have proposed an intramolecular hydrogen atom abstraction as the key step in

Scheme 55 Synthesis of a peptide via Baeyer–Villiger reaction of a β -lactam with TEMPO and bleach.

the Cu/TEMPO catalytic aerobic cycle^{281,282}; however, calculations support a possible ionic hydride transfer mechanism^{38,283} (Scheme 56). After alcohol oxidation, the resulting Cu(I) and TEMPOH are reoxidized by O_2 to Cu(II) and TEMPO, respectively.

Several ligands, such as 2,2'-bipy,^{281,282,284} 1,10-phenanthroline (phen),²⁸⁵ pyrazole derivatives,²⁸⁶ and DABCO,²⁸⁷ as well as bases such as *t*-BuOK,^{281,282} NaOH,^{281,285} KOH,^{281,284} and DBU²⁸⁴ have been utilized in copper complex-mediated aerobic oxidation of alcohols. Under one set of conditions, no base was required, and the Cu(II) complex could be reused thrice without loss of reactivity.²⁸⁸ The use of a dinuclear Cu(II) complex was reported, but only works with primary benzylic alcohols.²⁸⁹ Recently, a Cu(II) complex immobilized on a silica support was utilized in supercritical carbon dioxide (scCO₂).²⁹⁰ These copper-mediated oxidations are selective, giving very good yields with primary benzylic and allylic alcohols, and in a few cases with secondary benzylic alcohols.²⁸⁵ There are a few reports in which primary aliphatic alcohols can be used.^{281,288} Recently, TEMPO/Cu has been employed in the aerobic oxidative rearrangement of a tertiary allylic alcohol.²⁹¹

Scheme 56 Two proposed mechanisms for Cu/TEMPO cocatalyzed aerobic oxidation of alcohols: (a) via an intramolecular hydrogen atom transfer and (b) via hydride transfer to an electrophilic Cu/TEMPO complex.

In contrast with copper, catalytic TEMPO/RuCl₂PPh₃ at 100 °C is effective for the aerobic oxidation of a broad range of alcohols, including aliphatic alcohols.^{278,292} The autooxidation of aldehydes to carboxylic acids under these conditions is completely suppressed by TEMPO, which acts as a carbon free radical scavenger. However, alcohols containing heteroatoms such as nitrogen cannot be oxidized by this system, as they deactivate the ruthenium catalyst by coordination as ligands.⁷⁵ This aerobic Ru/TEMPO system was shown to convert α -hydroxy ketones into 1,2-diketones, which were trapped *in situ* with aromatic 1,2-diamines to form quinoxalines (Scheme 57).²⁹³

From mechanistic studies on the Ru/TEMPO system, RuCl₂(PPh₃)₃ gets reduced to RuH₂(PPh₃)₃, possibly by oxidation of a small amount of alcohol (Scheme 58).⁷⁵ Reaction with 2 equiv of TEMPO forms TEMPOH and the ruthenium alkoxyamine complex **a**. The piperidinyloxy ligand in complex **a** is displaced by alcohol to form another equivalent of TEMPOH and complex **b**, which undergoes the key β -hydride elimination, to afford the carbonyl product and regenerating the RuH₂PPh₃ catalyst.

Interestingly, Liang *et al.* have investigated the use of an inexpensive and environmentally friendly TEMPO/FeCl₃/NaNO₂ system^{294,295} to oxidize

Scheme 57 Oxidation of α -hydroxy ketones with Ru/TEMPO, followed by trapping with 1,2-diamines to form quinoxalines.

Scheme 58 Proposed mechanism for the Ru/TEMPO catalyzed aerobic oxidation of alcohols.

a broad range of alcohols including aliphatic alcohols under ambient conditions, in contrast to the TEMPO/ $\text{RuCl}_2\text{PPh}_3$ system which requires heating to 100°C .²⁷⁸ Further optimization of these

reaction conditions has been explored by several groups.^{295,296} An iron-activated electrophilic TEMPO complex involving a hydrogen abstraction pathway reminiscent of the Cu(II)/TEMPO system is likely. The catalytic cycle involves the oxidation of Fe(II) to Fe(III) by NO_2 and the oxidation of TEMPOH to TEMPO by Fe(III). The stoichiometric oxidant, molecular oxygen, regenerates the NO_2 .

5.3.2 TEMPO Reactions with Phenols and Catechols

TEMPO and derivatives oxidize phenols and catechols, such as 3,5-di-*tert*-butylcatechol,²⁹⁷ 2-aminophenol,²⁹⁸ L-tyrosine,²⁹⁹ and *o*-phenylenediamine³⁰⁰ via hydrogen atom abstraction under aerobic conditions. A proposed mechanism for the oxidation of 3,5-di-*tert*-butylcatechol is shown in Scheme 59. Semiquinone radical, produced by hydrogen abstraction by TEMPO of the very activated catechol OH, is readily trapped by molecular oxygen to give a peroxy radical. This peroxy radical in turn abstracts hydrogen atom

Scheme 59 Proposed mechanism for aerobic TEMPO-catalyzed 3,5-di-*tert*-butylcatechol oxidation.

back from TEMPOH to regenerate TEMPO. The hydroperoxide intermediate breaks down to form quinone and hydrogen peroxide.

5.3.3 Electron-Poor Nitroxides

Fremy's salt, potassium nitrosodisulfonate, was the first reported nitroxide. The applications of Fremy's salt in synthesis have been reviewed by both Zimmer³⁰¹ and Parker³⁰² and include the oxidation of heteroatom-substituted aromatic compounds, such as phenols,^{303,304} naphthols, indoles,³⁰⁵ carbazoles, quinolines,³⁰⁶ benzylic alcohols,³⁰⁷ and α -amino and α -hydroxy acids.^{308,309} In the oxidation of phenols to benzoquinones,³¹⁰ very electron poor Fremy's nitroxide abstracts the phenolic hydrogen to give a resonance-stabilized phenoxy radical intermediate (Scheme 60). This delocalized radical is trapped at carbon with another Fremy's nitroxide, followed by elimination of the aminosulfonate group to provide the *ortho*- or *para*-benzoquinones. Amino acids can be oxidized by Fremy's salt, followed by hydrolysis to the corresponding α -keto acids (Scheme 61).³⁰⁹ Oxidation of phenols or anilines to quinines by Fremy's salt has been used in the total synthesis of several biologically active compounds.^{311–314}

In contrast to stable dialkyl nitroxides, the diacyl nitroxide PINO, generated from *N*-hydroxyphthalimide (NHPI) (Scheme 62), is far more reactive at hydrogen atom abstraction than TEMPO due to the higher bond dissociation energy of NO–H bond in PINO–H.³¹⁵ The electron withdrawing carbonyl groups destabilize the diacyl nitroxide, but increase the stability of the hydroxylamine via intramolecular hydrogen bonding.⁷ The reactivity of PINO can be tuned by adding substituents to the aromatic moiety.³¹⁶ PINO in combination with *m*-chloroperbenzoic acid, $(\text{NH}_4)_5\text{H}_6\text{PV}_8\text{Mo}_4\text{O}_{40}$, or $\text{Co}(\text{OAc})_2$ and O_2 (the Ishii system) as an initiator has been used to oxidize alcohols to aldehydes or ketones^{75, 317–321} to oxidatively cleave benzylidene acetals³²² and to effect the autooxidation of unactivated alkanes and alkyl aromatics.^{318, 323–325} For example, aerobic oxidations to prepare commercially important fine chemicals, such as benzoic acid³²⁶ and nicotinic acid (vitamin B_3),³²⁷ can be performed in acetic acid under relatively mild conditions. A suggested

Scheme 60 Mechanism for the oxidation of phenol to benzoquinone with Fremy's salt.

mechanism in the presence of peroxide as an initiator is shown in Scheme 62.³²⁸ Initiation involves formation of a radical species, followed by abstraction of hydrogen atom from NHPI to form PINO, which then propagates the radical chain.

The nitroxide generated from *N,N',N''*-trihydroxyisocyanuric acid (THICA) (Figure 4) can be more effective than PINO in hydrogen abstraction, probably due to the greater stability of the corresponding nitroxide against decomposition.³²⁹ *N*-Hydroxysaccharin (NHS)

Scheme 61 Mechanism for the oxidation of amino acids to α -keto acids with Fremy's salt.

Scheme 62 Mechanism of autooxidation catalyzed by NHPI/peroxide.

Figure 4 Precursors to highly reactive (nonpersistent) nitroxides utilized in autooxidation.

(Figure 4), in which one carbonyl group of NHPI has been replaced by the more strongly electron withdrawing sulfonyl group, was shown to be a highly effective catalyst in the autooxidation of large-ring cycloalkanes,^{330,331} under conditions

where PINO did not work. NHS also catalyzes oxidation at benzylic positions, in addition to primary and secondary alcohols³³¹; however, the rates are lower than that with NHPI.³¹⁷

In contrast to electron-poor nitroxides, hydrogen atom abstraction by TEMPO under normal reaction conditions is not efficient due to the weak O–H bond in TEMPOH. However, on photoexcitation, TEMPO is much more reactive and is able to abstract hydrogen atoms from solvents such as toluene, xylene^{332,333} and acetonitrile³³⁴ as well as cyclohexene,^{335–337} phenols,^{338,339} and even unactivated hydrocarbons.³⁴⁰ However, the use of photoexcited nitroxides in hydrogen abstraction reactions has not yet been developed into synthetically viable procedures.

6 CONCLUSIONS

The use of nitroxides in synthetic organic chemistry has blossomed over the past 15 years. While nitroxides were largely used as spin labels in the past, nitroxides are now common reagents in synthesis, operating as oxidizing agents, and carbon radical traps. The oxoammonium salts act as both electrophiles and single electron oxidants, whereas the hydroxylamine anions act as both nucleophiles and single electron reductants. In redox processes, the nitroxide can often be used in catalytic amounts, allowing the use of inexpensive primary oxidants. Applications to the oxidation of organic molecules, metal catalysts, and metal complexes are growing at an accelerating rate. Electron-poor nitroxides take part in a different manifold of reactions, abstracting hydrogen atoms in a variety of processes (including autooxidation), and adding to unsaturation. A

number of highly designed nitroxides are emerging with specific properties, ranging from bridged, sterically unhindered nitroxides, nitroxides bearing an α -hydrogen (providing a slow but important decomposition pathway), electron-poor nitroxides, and nitroxides with appended functionality, including fluorophores, solubility tags, and reactive groups to allow for further synthetic elaboration. The commercial availability of TEMPO makes it the most popular of the nitroxide reagents; however, as the chemistry becomes highly developed, it is inevitable that a variety of nitroxides will become regular reagents in the synthetic organic laboratory.

Biological Chemistry of Reactive Oxygen Species

Christine C. Winterbourn

Department of Pathology, University of Otago Christchurch, Christchurch, New Zealand

1 INTRODUCTION

Free radicals and other reactive oxygen species (ROS) are produced in a wide range of physiological processes. They are capable of inflicting biological damage and are implicated in aging and the pathology of many conditions including cancer, cardiovascular, inflammatory, and degenerative diseases. Whereas the traditional way of thinking is that they are a necessary evil of living with oxygen in our environment, it is now apparent that they are also produced intentionally by living organisms and used to regulate processes such as cell growth and differentiation. Within this context, the objective of this article is to discuss the free radicals and other reactive oxidants that are most relevant in biology, how they are formed, their reactivity, and how we can assess which reactions are likely to be of biological significance. There is an extensive literature on this topic and some aspects have been covered only briefly and reference to recent reviews is made. For more extensive coverage, Halliwell and Gutteridge's book, *Free Radical Biology and Medicine*¹ is highly recommended. Interactions of free radicals with DNA, proteins, lipids, and other classes of biomolecules are also the focus of subsequent articles of this encyclopedia (see **Oxidatively Generated Nucleobase Modifications in Isolated and Cellular DNA, Oxidatively Formed Sugar Radicals in Nucleic Acids, Reactions of Small Reactive Species with**

DNA, Oxidative Damage to Proteins, and Lipid Peroxidation).

Biologically relevant ROS include radicals and non-radical species. The term *ROS* is widely used to encompass oxygen radicals and non-radical derivatives of oxygen (Table 1). Alternative terms are sometimes used, including reactive oxidants, oxygen-derived species, and reactive species, which is expanded to include other reactive derivatives of, for example, sulfur, nitrogen, and chlorine. However, "reactive oxygen species" is my preference, as the first alternative is not strictly correct because species such as superoxide can act as reductants, the second loses the notion of reactivity, and the latter definition becomes so broad as to cover most molecules. The initial species generated by oxygen reduction as well as their secondary reactive products are generally considered as ROS. Although there are radicals (e.g., thiyl or carbon-centered radicals) that do not strictly fit into this classification, their interactions frequently involve oxygen and link them to the overall ROS network.

The advantage of considering ROS in a broad context is that many of the species included in the definition are derived from one another or exist in equilibrium, so it is often not possible to consider one in isolation. However, it is equally important that "ROS" not be considered as a single entity. As discussed below, individual ROS vary widely in their reactivity and do not necessarily react with the same targets. So although the term

Table 1 Major reactive oxygen species (ROS) in biology.

Radical		Non-radical
Superoxide	$O_2^{\bullet-}$	Partially reduced oxygen
Hydroxyl	$OH^{\bullet}$	Hydrogen peroxide
		H_2O_2
Phenoxy	$PhO^{\bullet}$	Oxygenated species
Alkoxy	$RO^{\bullet}$	Singlet oxygen
Hydroperoxyl	$ROO^{\bullet}$	Hydroperoxide
Semiquinone	$O=Ph-O^{\bullet-}$ ($SQ^{\bullet-}$)	Hypochlorous acid
Carbonate	$CO_3^{\bullet-}$	Hypobromous acid
		Hypothiocyanous acid

Nitric oxide	$NO^{\bullet}$	Peroxynitrite
Nitrogen dioxide	$NO_2^{\bullet}$	$ONOO^-$

R, alkyl; Ph, phenyl.

^aHOCl, HOBr, and HOSCN can also be classified as halogenated (or pseudohalogenated) species.

is appropriate for describing a general class of compounds, grouping all ROS together is counterproductive for understanding mechanisms. This is not uncommon, and can result in unrealistic roles being proposed for the involvement of ROS in biological phenomena.²

2 HISTORY

The existence of free radicals as chemical species was recognized over a hundred years ago and the process of rancidity, or lipid peroxidation, has been known for centuries (see **The History of Free Radical Chemistry**). Major developments in the biology of free radicals began around the 1950s. Largely through the application of research from the rubber industry to food science (see **Basic Concepts on Radical Chain Reactions**), the free radical chain reaction of lipid peroxidation was recognized, and from the intense research activity generated around nuclear energy, the fundamental role of radicals in radiation chemistry was recognized. The relevance of these mechanisms to living organisms was first highlighted by two pioneering publications. In 1954, Rebecca Gershman, Daniel Gilbert, and colleagues³ published their classic paper "Oxygen poisoning and X-irradiation: A mechanism in common" and in 1956 Denham Harman⁴ proposed his free radical theory of aging. These ideas stimulated others to consider free radical processes as potential

pathological mechanisms.^{5,6} However, it was the discovery of the enzyme superoxide dismutase (SOD) by Fridovich and McCord⁷ in 1969, which really opened up the field. The existence of an enzyme that breaks down superoxide radicals led to the realization that free radicals are widely generated in biological systems and the finding that organisms require SOD to survive in an aerobic environment⁸ added weight to the proposal that oxygen radicals are responsible for the toxic effects of oxygen. Furthermore, SOD became available as a powerful tool for investigating their role. It was a surprise at the time to discover that the biological reactivity of superoxide is modest, and although deleterious reactions have been identified, the nature of its toxicity is still debated today.

There have been substantial advances since then, especially in the understanding of how free radicals and other ROS react with different classes of biomolecules and how these reactions inflict biological damage. The field has also moved in an unexpected direction from the original concept that free radicals are unwanted toxins to be disposed of at all costs, as it became realized that organisms generate ROS in regulated cellular processes. A number of seminal findings have influenced this way of thinking. First, it was shown that white blood cells (neutrophils) intentionally produce hydrogen peroxide⁹ and superoxide¹⁰ to kill microorganisms. While ROS still act as toxins in this role, observations that exposure to low levels of superoxide

and/or hydrogen peroxide induce positive responses such as cell growth and differentiation, as initially highlighted by Burdon,¹¹ led to the realization that ROS are not strictly deleterious. This view was reinforced by the finding that the NADPH oxidases that produce superoxide in phagocytic cells are widely expressed in other cells and are responsive to growth factors and hormones.^{12,13} Numerous investigators have extended these findings and redox regulation of cell signaling is currently a very active research field.¹⁴ Another notable (Nobel prize winning) discovery that revolutionized physiology was that the free radical gas, nitric oxide, is generated endogenously and regulates numerous metabolic processes.^{15,16}

For all this scientific endeavor and knowledge acquisition, there are still uncertainties about the role of ROS in biology. Although excess production of free radicals is known to be damaging and antioxidant defense mechanisms are essential to protect against them, there are relatively few cases (mainly relating to specific toxicities) where free radicals or other reactive oxidants have been shown to cause a particular pathology or disease. Similarly, health benefits through pharmacological intervention have been largely unrealized.

3 OXYGEN AND EVOLUTION OF LIFE

ROS are intimately linked to the evolution of life on earth.¹⁷ The early atmosphere in which anaerobes evolved was strongly reducing, with most of the oxygen tied up as water. From this environment arose photosynthetic organisms capable of harnessing light energy to convert water to oxygen, and oxygen gradually accumulated. Aerobes that could use the energy released by metabolic reduction of oxygen to water through respiration then developed. However, photosynthesis and respiration are not perfect at interconverting oxygen and water directly, and some partially reduced intermediates (superoxide and hydrogen peroxide) are released. Without systems for handling these reactive species, aerobic organisms would not have survived. Even when there was no molecular oxygen, ROS would have been generated through processes such as UV radiation-induced breakdown of water. An intriguing proposal is that the development of catalase-like molecules using the abundant iron in the environment was critical for early life

forms to survive their deleterious effects.¹⁸ In this scenario, antioxidant mechanisms would have preceded the accumulation of oxygen in the atmosphere and been vital for the initial development of aerobic life. So controlling the effects of ROS could be considered a trade-off for the advantages of metabolizing oxygen, and an extensive array of antioxidant systems have developed for this purpose.

4 BIOLOGICAL SOURCES OF REACTIVE OXYGEN SPECIES

There are a number of cellular processes that generate free radicals and other ROS. Major sites of ROS generation are depicted in Figure 1.

4.1 Mitochondria

Mitochondrial respiration is a major biological source of ROS.¹⁹ Although most of the oxygen consumed by mitochondria is reduced directly to water by cytochrome oxidase, some electrons do leak out of the electron transport chain. Oxygen is reduced to superoxide, which is released into the mitochondrial matrix. It is often reported that up to 5% of the oxygen consumed is converted to superoxide. However, this is probably an overestimate because many of these measurements have been made using methods that promote superoxide release and thus distort the system.¹⁹ The main site of superoxide formation is complex I (NADH-ubiquinone oxidoreductase) under conditions where the ratio of NADH : NAD is high or where conditions favor reverse electron transport (Figure 2). The reaction of oxygen with the ubisemiquinone radicals generated from complex III (ubiquinone-cytochrome reductase) is another, probably less significant source, as are other mitochondrial enzyme systems such as α -ketoglutarate dehydrogenase. As in other situations where superoxide is produced, hydrogen peroxide is also formed either by spontaneous dismutation or in a reaction catalyzed by SOD (1).

Figure 1 Prototype animal cell showing sites of generation of reactive oxygen species.

Figure 2 Sites of ROS generation during mitochondrial electron transport. Complex I (NADH-ubiquinone oxidoreductase) oxidizes NADH using coenzyme Q (Q) as an electron acceptor in a reversible reaction. Complex II (succinate-ubiquinone oxidoreductase) oxidizes succinate to fumarate using CoQ as an electron acceptor. Complex III (ubiquinone-cytochrome c oxidase) oxidizes CoQ using cytochrome c (C) as an electron acceptor. Complex IV (cytochrome c oxidase) is the site of reduction of oxygen to water. The reactions at complexes I, III, and IV are coupled with the translocation of protons out of the matrix to generate a transmembrane potential, which is used by the F₁F₀-ATPase to generate ATP. α-KGDH, α-ketoglutarate dehydrogenase.

4.2 NADPH Oxidases

Important biological source of superoxide and hydrogen peroxide, particularly within the context of cell signaling, are the NADPH oxidases (NOXs).

These are a family of multiprotein complexes that catalyze the transfer of electrons from NADPH to oxygen to produce superoxide.²⁰ The prime function of these enzymes is understood to be the production of superoxide (or hydrogen peroxide). There

are five NOX family members, each containing a cytochrome b and a flavoprotein but with different regulatory subunits, cellular localization, and modes of activation.²¹ There are also two DUOXs, which are related proteins termed *dual oxidases* because they also contain a peroxidase domain (which may or may not be active).²² DUOX activity in the thyroid gland is required to provide the hydrogen peroxide used by thyroid peroxidase for hormone synthesis. NOXs are present in animals, plants, and fungi, and have diverse physiological functions.¹³ Most release superoxide directly and it dismutates to give hydrogen peroxide; in others (e.g., NOX4) hydrogen peroxide is formed from the superoxide before it leaves the active site.²³ NADPH oxidases are membrane associated,²⁴ and an important aspect of their cell biology is that electron flow is directional. Thus NADPH is oxidized in the cytoplasm and superoxide is released on the external side of the membrane. This may be to the outside of the cell, or if the membrane is internal, as is the case for the neutrophil phagosome (see below), into the encapsulated organelle (Figure 3a).

4.2.1 Phagocytes

Until recently, the only known NADPH oxidase (now designated NOX2 isoform) was in phagocytic cells (neutrophils and monocytes), where it is required for killing microorganisms.^{26,27} When these cells ingest microorganisms (phagocytosis), NOX2 is activated to generate a high flux of superoxide radicals into the phagosomal space (Figure 3a). In neutrophils, most of the hydrogen peroxide (formed by dismutation of superoxide) reacts with myeloperoxidase which is also released into the phagosome. Myeloperoxidase, and the related peroxidase in eosinophils,²⁸ oxidize halide ions as well as a wide range of more traditional peroxidase substrates. The most significant reaction of myeloperoxidase in the phagosome is with chloride to give hypochlorous acid.^{29,30} Although the precise mechanism of killing is not fully understood, hypochlorous acid is the neutrophil's most effective antimicrobial oxidant.²⁶ The directionality of NOX activity (Figure 3a) means that transfer of electrons occurs across the membrane to oxygen in the phagosomal space. This creates a charge imbalance that

Figure 3 Oxidant generation by NADPH oxidases. (a) Neutrophil phagosome following ingestion of a bacterium. The NADPH oxidase (NOX2) is activated on the phagosomal membrane; electrons are transported from NADPH across the membrane to oxygen to generate superoxide radicals that dismutate to hydrogen peroxide. Degranulation releases (along with other proteins) myeloperoxidase, which generates hypochlorous acid. (b) Proposed mechanism for oxidant generation from receptor-mediated NOX activation illustrated for NOX1 in angiotensin II-activated smooth muscle cells. Receptor activation causes components of the NOX complex to assemble in regions of the membrane (in this case caveoli). Intracellular NADPH is consumed and superoxide is generated on the external surface.²⁰ [Reproduced from Ref. 25. © Nature Publishing Group, 2008.]

must be compensated, mainly by proton movement through voltage-gated channels.³¹ An interesting proposal is that this electrogenic effect, rather than oxidant production accounts for the antimicrobial effect of NOX2, by creating a favorable ionic environment for other antimicrobial agents released into the phagosome.^{32,33} However, this view has been challenged and the bulk of evidence strongly favors an oxidative killing mechanism.^{26,31} Nevertheless, the consequences of electron translocation across the membrane due to NOX activity need further clarification.³⁴

NOX activation can be induced by other stimuli in the absence of phagocytosis, with the reactive oxidants released into the surroundings of the cells.³⁵ This could be considered the downside of oxidative killing as many biological molecules are vulnerable to attack by neutrophil oxidants and excessive production in chronic inflammatory conditions can result in oxidative damage to host tissue.^{36–38}

4.2.2 Non-Phagocytic Cells

NOX activity in other cell types is generally at a much lower capacity than in phagocytes, and rather than having an antimicrobial function, is involved in cell signaling.^{20,27} Although some NOXs are constitutively active, activation is mostly receptor-mediated. Depending on the isoform, organism, and cell type, activation can be by hormones, cytokines, shear stress, or growth factors,^{39–41} and have diverse effects including cell growth and differentiation, production of inflammatory mediators, hyphal growth in fungi, and root hair growth in plants.^{13,42} Where cell localization studies have been performed, NOX assembly has been shown to occur at specific membrane sites, such as in caveolae (as in Figure 3b), lipid rafts, or endosomes.^{20,23,24,43} Superoxide should therefore be generated extracellularly or within the endosome. The implication is that oxidant action also occurs at localized sites in the cell. Studies with hydrogen peroxide-specific probes are starting to provide some direct evidence for this.⁴⁴ As discussed below, there is still uncertainty about how superoxide or hydrogen peroxide transmits signals associated with NOX activation. The prevailing view is that thiol proteins are the major targets and that redox changes link to phosphorylation pathways of signal transduction.

4.3 Flavoprotein Oxidases

Hydrogen peroxide is generated in reactions catalyzed by a range of flavoprotein oxidases, in equimolar amounts to the substrate that they oxidize (2).

Many of these enzymes, for example, acyl-CoA oxidase, polyamine oxidase, urate oxidase, xanthine oxidase, plant glycolate and sulfide oxidases, are present in peroxisomes.^{45,46} These organelles contain most of the cellular catalase, and therefore have a high capacity to break down hydrogen peroxide, but any that escapes could still be a major peroxide source for the rest of the cell. Peroxisomes also contain other antioxidant enzymes including SOD, so in different situations could act as a source or sink for ROS.⁴⁵

Other significant sources of hydrogen peroxide are the flavoprotein oxidases (such as ERO1) present in the endoplasmic reticulum (ER).⁴⁷ These proteins are required for oxidative folding of exported proteins and catalyze the oxidation of Cys residues by molecular oxygen to form protein disulfide bonds (Figure 4).⁴⁸ With a 1 : 1 stoichiometry per disulfide, large amounts of hydrogen peroxide could theoretically be produced.⁴⁹ Although this has not yet been detected directly, a rate of ~ 1 mM/min can be calculated for antibody-producing plasma cells.⁵⁰ How the ER handles hydrogen peroxide, and whether any is released into the cytoplasm, are questions that are currently being addressed. One possibility is that it is consumed by peroxiredoxin 4, which is also localized in the ER.⁵¹ Thus, hydrogen peroxide formation by flavoproteins in the ER or peroxisomes occurs without requiring an external stress or stimulant and in some situations these organelles could be the major cellular site of peroxide generation. How this activity relates to peroxide generation from NADPH oxidases during cell signaling is an important question that is yet to be resolved.

4.4 Heme Protein Autoxidation

Superoxide and/or hydrogen peroxide is produced by other oxygen-utilizing proteins. For example,

Figure 4 Proposed mechanism for hydrogen peroxide formation during oxidative protein folding in the endoplasmic reticulum. ERO1, endoplasmic reticulum oxidoreductin 1; PDI, protein disulfide isomerase.

autoxidation of heme proteins such as hemoglobin (Hb; 3), myoglobin, or nitric oxide synthase results in release of the bound oxygen as superoxide.^{52,53} The hemoglobin in the erythrocyte is estimated to autoxidize at a rate of a few percent of per day, so is an appreciable source of superoxide in these cells.

4.5 Radiation

Free radicals are produced on exposure of biological systems to ionizing or UV radiation and are directly or indirectly responsible for the toxicity of such exposure. As described in more detail elsewhere,⁵⁴ the primary target for ionizing radiation is water, which is split into hydroxyl radicals, hydrogen atoms, and hydrated electrons. The latter two species are strongly reducing and short lived and in aerobic solution react primarily with oxygen to give superoxide. Although direct attack of the radiation can also generate radicals on macromolecules such as DNA (see **Oxidatively Generated Nucleobase Modifications in Isolated and Cellular DNA and Understanding DNA Radicals Employing Theory and Electron Spin Resonance Spectroscopy**), the majority of the biomolecular damage is due to hydroxyl radicals, superoxide, and secondary products.

Photochemical ROS generation by UV radiation is particularly important for photoinduced damage to the skin and eye in mammals,⁵⁵ and in the plant chloroplast during photosynthesis.⁵⁶ Most photochemistry occurs via photosensitizers (e.g., chlorophyll, porphyrins) which are converted to

an excited state, whereas lower wavelength UV radiation can form radicals on target molecules directly. As discussed elsewhere,^{1,55,56} ROS generation occurs by energy transfer to oxygen to give singlet oxygen (type I mechanism) or via a radical (type II) mechanism that produces superoxide and other reactive species.

4.6 Drugs and Xenobiotics

Metabolic oxidation or reduction to free radicals is a common toxicological mechanism for a wide spectrum of drugs and xenobiotics. Quinones and related species are reduced by flavoenzymes such as cytochrome *P*450 reductase, ferredoxin reductase, or xanthine oxidase to generate semiquinone-like species.^{57,58} These radicals commonly react with oxygen to generate superoxide and the parent compound, in a process known as *redox cycling*.⁵⁹ Reducing equivalents are supplied by the cosubstrate of the enzyme (usually NADPH) and the xenobiotic effectively catalyzes the reduction of oxygen to superoxide. Examples of redox cycling agents are the herbicide paraquat, menadione (4), the anticancer drug doxorubicin, and the diabetogenic compound alloxan.^{60–63}

Scheme 1 Reaction of phenylhydrazine with oxyhemoglobin.

Other compounds, including phenols and aromatic amines, are oxidized to radicals by peroxidases such as myeloperoxidase or lactoperoxidase. Endogenous compounds, including tyrosine (5), serotonin, urate, nitrite (6), and ascorbate are good peroxidase substrates.^{64,65} Polyphenols, such as the flavonoids, that are commonly classified as dietary antioxidants also react with peroxidases to form radicals,⁶⁶ and such pro-oxidant reactions could counteract their radical-scavenging antioxidant activity in some situations. Drugs such as phenothiazines and clozapine are oxidized by myeloperoxidase and radical-mediated injury can contribute to their adverse side reactions.^{67,68} Polycyclic hydrocarbons, carcinogens, and benzene can also be activated by cytochrome *P*450 to phenolic derivatives which are oxidized by peroxidases to their phenoxyl radicals.^{69,70} Heme proteins, such as hemoglobin and cytochromes, can also act as peroxidases.^{71,72} As these proteins tend to be abundant, their reactions are biologically relevant even though much less efficient.

Heme proteins and transition metal ions also promote free radical formation by catalyzing auto-oxidation reactions. These reactions, along with hydroxyl radical production (see later), are important mechanisms in metal toxicity. Interactions with hemoglobin give rise to some of the most clear-cut

cases of oxidative stress-related disease.^{52,73} The prototype reaction is with phenylhydrazine, which is oxidized by the heme-bound oxygen initially to give the hydrazyl radical, ferric heme, and hydrogen peroxide (Scheme 1). The radical can then react with oxygen to generate superoxide and these species plus a series of secondary products cause oxidative damage to the erythrocyte. They can be handled by normal erythrocytes, but individuals with an inherited deficiency of the enzyme glucose-6-phosphate dehydrogenase are unable to generate the reducing equivalents (NADPH) needed for the effective removal of hydrogen peroxide and reversal of oxidative changes. They suffer from severe hemolytic anemia if they take antimalarial drugs such as primaquine (where a metabolite is the active agent), sulfanilamides, dapsone, and other substituted aromatics.⁷⁴ Some individuals are particularly susceptible to fava beans, which contain the readily oxidizable hydroxypyrimidines, divicine, and isouramil.^{75,76}

5 PROPERTIES OF REACTIVE OXYGEN SPECIES

Individual ROS differ in their chemical and physical properties. Some are strong and others weak oxidants; some are radicals and undergo one-electron reactions, whereas others are non-radical species that cause two-electron oxidation; they vary in their membrane permeability and in their ability to be scavenged by individual antioxidants. Therefore, the biological impact of ROS production will depend on what species are produced and where. The picture is complex, because many of these species are derived from one another and many of the reactions are reversible (Figure 5), but for a mechanistic understanding of biological processes, it is important to decipher what specific ROS are involved.

For the most part, ROS act as oxidants. However, because the direction of any redox reaction depends on the reduction potentials of the couples involved,

Figure 5 Interplay of physiologically relevant reactive oxygen species. The scheme covers most reactive species (or representatives of a class) and selected routes of generation or interconversion. Abbreviations as in Table 1. One-electron oxidants (radicals) are shown in red and two-electron oxidants in blue. [Reproduced from Ref. 25. © Nature Publishing Group, 2008.]

a species (superoxide, for example) can be an oxidant in some situations and a reductant in others. A more detailed description of the relevant thermodynamics can be found elsewhere (Ref. 77 and **Redox Properties of Radicals**) but in brief, for a reaction to proceed, there must be a negative change in the Gibbs free energy (ΔG). This is related to the difference in reduction potential of the two couples ($\Delta G = -nF\Delta E$, where E is the reduction potential, F the Faraday constant, and n the number of electrons involved). Under any set of conditions, E is a function of the standard reduction potential (E° , or often more conveniently expressed as $E^{o'}$ at pH 7) and the reactant and product concentrations. It is described by the Nernst equation (T temperature, R the gas constant, F Faraday constant, $2.303 RT/F = 0.059$ at 278°K).

$$\text{For } A + ne \longrightarrow B \quad E(V) = E^\circ + 2.303RT/nF \log[B]/[A]$$

(and at 278°K ; $n = 1$) $= E^\circ + 0.059 \log[B]/[A]$

As a general guideline for a reaction between two redox couples, the couple with the higher $E^{o'}$ will act in an oxidizing direction. In Table 2, hydroxyl radicals are the most oxidizing, and radicals higher up the table are more likely to act as oxidants. An alkoxyl radical will oxidize a phenol for example. However, as reactant and product concentrations also influence the direction of a reaction, under some conditions (e.g., if products are rapidly removed), a radical lower down the table can act as the oxidant.

Table 2 One-electron reduction potentials of a selection of biologically relevant free radicals.

Radical couple	Reduction potential ($E^{o'}$) V
$\text{OH}^\bullet, \text{H}^+/\text{H}_2\text{O}$	2.31
$\text{CO}_3^{\bullet-}, \text{H}^+/\text{HCO}_3^-$	1.78
$\text{RO}^\bullet/\text{RO}^-$	~ 1.60
$\text{NO}_2^\bullet/\text{NO}_2^-$	1.04
$\text{O}_2^{\bullet-}/2\text{H}^+/\text{H}_2\text{O}_2$	0.94
$\text{PhO}^\bullet, \text{H}^+/\text{PhOH}$	0.90
$\text{CysS}^\bullet/\text{CysS}^-$	0.92
$\text{ROO}^\bullet, \text{H}^+/\text{ROOH}$	0.77–1.44
Catechol $\text{SQ}^{\bullet-}, \text{H}^+/\text{catechol}$	0.53
Quercetin $\text{SQ}^{\bullet-}, \text{H}^+/\text{quercetin}$	0.33

Species are listed in an approximate order of decreasing reactivity. Standard reduction potentials ($E^{o'}$) are at pH 7, relative to normal hydrogen electrode, and are from Refs 77 and 78. Abbreviations or formulae for radicals are from Table 1. Note that $\text{O}_2^{\bullet-}$ is in equilibrium (pK_a 4.8) with the hydroperoxyl radical ($\text{HO}_2^\bullet$); $E^{o'}$ 1.06 V and that $\text{O}_2^{\bullet-}$ ($\text{O}_2/\text{O}_2^{\bullet-}$ $E^{o'} -0.33$ V) and semiquinones can also act as reductants. Reduction potentials of different phenoxyl radicals and semiquinones vary depending on substituents.

Furthermore, thermodynamics only tell whether a reaction is feasible, not whether it will occur within a reasonable time frame. This depends on the activation barrier that must be overcome, which is reflected in the reaction kinetics (Figure 6).

5.1 Radical Reactions

Biologically relevant ROS include both radicals and two-electron (non-radical) oxidants (Table 1 and

Figure 6 Energy diagram illustrating kinetic versus thermodynamic considerations.

Figure 2). Radicals are not necessarily more reactive than non-radicals, but because the reaction of one radical with a non-radical generates another radical, they have the capacity to undergo chain reactions such as lipid peroxidation (see **Lipid Peroxidation**). Radical reactions are also more likely to be inhibited by phenolic antioxidants such as vitamin E and flavonoids, or ascorbic acid. As well as being a measure of oxidizing strength of a radical, one-electron reduction potential (as in Table 2) is a reasonable reflection of its reactivity because the activation energy for radical reactions is low.

The stronger the oxidant, the less discriminating it is. Hydroxyl radicals, for example, can oxidize DNA bases (see **Oxidatively Generated Nucleobase Modifications in Isolated and Cellular DNA**), aliphatic and aromatic amino acid residues (see **Oxidative Damage to Proteins**), sugars, and many other biomolecules.¹ Carbonate radicals are also capable of oxidizing many of these substrates.⁷⁹ These radicals are formed in the reaction of hydroxyl radicals or peroxy nitrite (see Section 5.2.2) with the carbon dioxide that is prevalent in physiological fluids, and from the peroxidase activity of metalloenzymes such as Cu/Zn SOD.^{79–81} Carbonate radicals are perhaps under-rated players in free radical biology.

Radicals with lower reduction potential, such as nitrogen dioxide, are more restricted but they can react with polyunsaturated lipids and the more oxidizable amino acids, cysteine, methionine, tyrosine, and tryptophan. Phenoxyl radicals vary in

oxidizing ability depending on their ring substituents.⁸² Polyphenols are more readily oxidized and form less energetic radicals that react poorly with these substrates,^{78,83} hence their ability to act as radical-scavenging antioxidants. Semiquinone radicals generally act as reductants and as noted above, reaction with oxygen leads to redox cycling and superoxide production.

Among the most sensitive biomolecules for radical attack are sulfur centers (Cys and Met residues), redox-active transition metals, and polyunsaturated lipids.^{1,84,85} These reactions do not require a highly oxidizing radical and can result in lipid peroxidation (see **Lipid Peroxidation**) and modifications that affect protein structure and activity. Oxidation can inactivate metalloproteins, and convert the metal into a secondary reactive species. More detail on these reactions and their consequences is presented in **Radical-Based Damage of Sulfur-Containing Amino Acid Residues and Oxidative Damage to Proteins**.

An important property of radicals is that they readily undergo reactions with other radicals. As examples, carbon-centered radicals react with diatomic oxygen (classified as a radical because of its two unpaired electrons) and radical recombination terminates the chain reaction of lipid peroxidation. The propensity for ascorbyl radicals to disproportionate to ascorbate and dehydroascorbate is key to ascorbate being an effective radical scavenger. Semiquinones also disproportionate, and phenoxyl radicals dimerize to give species such as

Scheme 2 Main route to nitrotyrosine.

dityrosine. Reaction of tyrosyl radicals with nitrogen dioxide (Scheme 2) is the major route to nitrotyrosine, and the very rapid reaction of nitric oxide with superoxide (7) is a mechanism for regulating nitric oxide levels and for forming the strong oxidant peroxynitrite.^{15,86}

Superoxide also reacts rapidly with other radicals.⁸⁷ These reactions can occur either by electron transfer to repair the parent compound (8) or addition. Addition reactions produce hydroperoxides, as shown for tyrosine (Scheme 3). In this case, the initial product undergoes conjugate addition with the α -amino group to give a reasonably stable hydroperoxide.^{88–90}

5.1.1 Superoxide

Superoxide can act as an oxidant and reductant. It is an unusual radical because in spite of its reduction

potential of 0.94 V, it oxidizes relatively few biological compounds. This is partly explained by its anionic charge-limiting reactivity with electron-rich centers and by its ready dismutation.¹⁷ Its protonated form, the perhydroxyl radical (pK_a 5.5), is a stronger oxidant. Superoxide reacts with ascorbate at an appreciable rate,⁹¹ and slowly oxidizes thiols such as reduced glutathione (GSH).⁹² Several mechanisms have been proposed to explain its toxicity.^{93,94} The best established is inactivation of iron/sulfur proteins such as aconitase and the dehydratases required for the synthesis of branched chain amino acids.^{94–96} One-electron oxidation by superoxide inactivates the enzymes and releases iron and hydrogen peroxide which can cause further injury (Scheme 4).^{97,98} These reactions are fast (rate constants $>10^6 \text{ M}^{-1} \text{ s}^{-1}$) and highly selective for superoxide.^{95,96} Oxidation of an iron/sulfur center is also employed by bacteria to upregulate resistance genes in response to sublethal superoxide. In this case, a [2Fe–2S] protein, SoxR, is oxidized, and a change in conformation transactivates the transcription factor, SoxS.⁹⁹

Another potentially detrimental reaction of superoxide is with nitric oxide to give peroxynitrite (7). This reaction has a rate constant of $\sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ and can compete with SOD-catalyzed dismutation.⁸⁶ Peroxynitrite (Section 5.2.2) is a reactive and damaging oxidant that is implicated in a range of pathologies.^{15,100} However, there is debate about whether sufficient peroxynitrite is generated physiologically for it to be a major toxic species^{15,101} and the reaction may be more relevant for modulating signaling by NO.^{102,103} Addition reactions with other radicals, such as the tyrosyl radical in the active site of ribonucleotide reductase, may also contribute to superoxide toxicity.^{87,104}

Scheme 3 Superoxide addition to tyrosyl radical to form hydroperoxide.

Scheme 4 Superoxide-mediated inactivation of iron–sulfur proteins.

SOD accelerates superoxide breakdown, but contrary to popular belief, does not necessarily increase the amount of hydrogen peroxide produced. Dismutation converts half the superoxide to hydrogen peroxide, regardless of whether or not it is catalyzed (1). SOD will only increase this amount if it prevents a reaction in which superoxide acts as a reductant or forms an addition product (such as 9 and 7) and does not generate hydrogen peroxide. If it prevents superoxide acting as an oxidant (e.g., as in Scheme 4), the amount of hydrogen peroxide produced would halve.

5.1.2 Nitric Oxide

Although a free radical, nitric oxide reacts slowly if at all with biological oxidants and reductants.¹⁵ It forms nitroso complexes with iron centers (as in its physiological role of activating guanylate cyclase) and is oxidized by oxyhemoglobin to nitrate or nitrite (10). This reaction is rapid and is the main route of removal from blood. Myeloperoxidase has also been shown to catalyze the removal of NO,¹⁰⁵ although this reaction may be mediated by other radical products of the enzyme.

Other major reactions of nitric oxide are addition reactions with other radicals including oxygen (11), superoxide (7), thiyl radicals (12), phenoxyl radicals,^{106–111} Nitrosothiol formation on protein thiols is emerging as an important cell regulatory mechanism.^{112,113} NO itself does not react directly with thiols but (12) provides a plausible mechanism

for nitrosothiol formation. Equation (11) involves an initial, reversible reaction between two NO molecules then reaction of the product with oxygen. The kinetics are therefore third order and it is poorly favored at low reactant concentrations.¹¹¹ It may have greater relevance in lipophilic environments where oxygen and nitric oxide are more soluble.¹¹⁴

5.1.3 Thiyl Radicals

Thiols are favored targets for a wide range of radical species. Radical scavenging by GSH is an important antioxidant defense, and oxidation of cysteine residues is also a mechanism for regulating the activity of thiol proteins. As discussed in more detail in **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**, the initial product is a thiyl radical (as in 13 for a generic radical R[•] and GSH). Thiyl radicals are themselves good oxidants and undergo a range of reactions including abstraction of hydrogen from protein residues and initiation of lipid peroxidation.^{115,116} They also undergo rapid reaction with another thiolate anion to form the disulfide radical anion (14). This reaction is an equilibrium that converts an oxidizing into a strongly reducing radical. In the presence of oxygen, it is driven in the forward direction to give the disulfide plus superoxide as final products (15). Physiologically, this is a major decay route for thiyl radicals. Alternatively, if the thiyl radical has limited access to another thiol, it can react with oxygen to form a peroxy radical (16) and a range of secondary products. Combination of two thiyl radicals to give the disulfide is generally not favored but can occur if oxygen is limiting. In

the presence of nitric oxide, nitrosothiol formation (12) is also possible. Thiyl radicals are readily scavenged by ascorbate.^{115,117}

In considering the role of GSH (or other thiols) as a radical scavenger, it is noteworthy that (13) is an equilibrium that in many cases lies to the left.¹¹⁵ On these grounds, GSH does not appear to have the qualities of a good radical-scavenging antioxidant. The reason why it is effective is that oxygen removes the disulfide radical anion via (15). Thus, oxygen enables GSH to act as a good scavenger without the buildup of potentially damaging thiyl radicals. The reaction also channels radicals into a pathway that leads to superoxide, which can be considered as a radical sink.¹¹⁶ This sequence provides an elegant mechanism for a single enzyme (SOD) to bring about radical removal.

5.2 Two-Electron Oxidants

The two-electron oxidants that are most relevant to biology are hydrogen peroxide, organic hydroperoxides, peroxyxynitrite, and the hypohalous acids. Although the strength of these oxidants is dictated by their reduction potential, kinetic considerations are more dominant in determining reactivity. Hydrogen peroxide, for example, has a higher reduction potential than hypochlorous acid (E° values of 1.77 and 1.50 for reduction to water and chloride, respectively), but reactions of hydrogen peroxide require much higher activation energy and rates are correspondingly slower. Rate constants for reaction with GSH (Table 3) give an indication of the relative reactivities of two-electron oxidants. As with radicals, thiol groups are among their most favored targets. The initial product is the sulfenic acid (or sulfenyl halide) which can undergo a range of secondary reactions that are not necessarily the same as for radical pathways.^{118,119}

Table 3 Relative reactivity of two-electron oxidants based on rate constants for reaction with GSH.

Oxidant	Rate constant ($\text{M}^{-1} \text{s}^{-1}$)
HOCl	3×10^7
HOBr ^a	1×10^7
HOSCN	8×10^4
ONOO ⁻	700
Chloramines	100–700
H ₂ O ₂	0.9

Rate constants are at pH 7 and are from Refs 120–125.

^aMeasured for *N*-acetylcysteine.

5.2.1 Hydrogen Peroxide

Under physiological conditions, hydrogen peroxide reacts poorly or not at all with most biological molecules, including low molecular weight antioxidants. It reacts slowly with typical thiols.¹²⁰ Its main reactions are with seleno-, thiol, or heme peroxidases and other transition metal centers to give both radical and non-radical species (Figure 5). Reactions with glutathione peroxidases, peroxiredoxins and ascorbate peroxidase are important for detoxification, whereas the radicals and other secondary products generated by metalloproteins, along with products of Fenton chemistry (Section 6.1), are major contributors to the biologically damaging effects of hydrogen peroxide.¹⁷ Cell signaling and oxidative stress responses to hydrogen peroxide are generally considered to involve direct reactions with specific thiol proteins.^{126–128} However, there are kinetic constraints on many of these reactions (Section 7.1) and radicals and other secondary peroxidation products may be involved in transmitting signals.

Organic peroxides are generally similar to hydrogen peroxide in their substrate preferences. They react readily with reduced or oxidized transition metal centers to generate alkoxyl or peroxy radicals, respectively and react directly with thiols. For some peroxiredoxins, they are better substrates than hydrogen peroxide, whereas for others, the reactivity is reversed. Based on data in Ref. 129 it would appear that amino acid hydroperoxides react slightly faster than hydrogen peroxide with GSH.

Hydrogen peroxide reacts with bicarbonate to form peroxymonocarbonate (17), which is approximately 100 times more reactive than free hydrogen peroxide.⁷⁹ This reaction could be biologically important as a mechanism for enhancing hydrogen

peroxide reactivity. However, the reaction is an equilibrium that lies to the left and the forward step is slow. So although this could be the case for pre-existing peroxydicarbonate, its rate of formation would quickly become limiting.

5.2.2 Peroxynitrite

The chemistry of peroxynitrite is complex and is well covered in recent reviews.^{15,86,111} Although peroxynitrite can act as a two-electron oxidant, its most favored biological reaction is with carbon dioxide (as shown in Figure 5) to form carbonate and nitrogen dioxide radicals. Most of its physiological effects are likely to be due to these secondary radicals. If carbon dioxide is limiting, peroxynitrite breaks down to hydroxyl radicals and nitrogen dioxide (see Figure 5). It is sufficiently reactive to oxidize thiols directly but at physiological concentrations, the reaction is a combination of direct and radical-mediated oxidation.¹³⁰ Peroxiredoxins have unusually high reactivity and should react directly with peroxynitrite.¹³¹

5.2.3 Hypohalous Acids

Hypohalous acids are generated from their corresponding halides (or in the case of hypothiocyanous acid from the pseudohalide, thiocyanate) by the mammalian peroxidases, myeloperoxidase, eosinophil peroxidase, and lactoperoxidase (as shown for chloride in Figure 5). These reactive oxidants mediate many of the biological effects of the peroxidases.^{30,37} They vary in oxidizing ability: hypochlorous > hypobromous > hypothiocyanous acid.^{132–134} The preferred substrates of hypochlorous acid are thiols and methionine residues, which react with rate constants greater than $10^7 \text{ M}^{-1} \text{ s}^{-1}$.^{121,135} Hypochlorous acid oxidizes numerous other substrates and also undergoes chlorination reactions, for example with tyrosine to form chlorotyrosine,¹³⁶ unsaturated lipids and NAD^+ to form chlorohydrins,^{137,138} and nucleotides to form chlorinated bases.¹³⁹ Chlorination reactions are much slower than oxidations but give rise to distinctive products that are useful biomarkers.^{140,141}

Hypobromous acid undergoes comparable reactions to hypochlorous acid, although the difference in reaction rate between oxidations and brominations is not as great as for hypochlorous acid.¹³³ Hypothiocyanous acid is capable of oxidizing thiols but undergoes few other biological reactions.^{122,134,142}

Hypochlorous and hypobromous acids react with amine groups to form chloramines and bromamines (Figure 5).^{143,144} Rate constants for these reactions are about 100-fold less than for thiols,^{123,133} but the biological prevalence of amine groups on free amino acids and proteins plus the fact that the products are also oxidants, mean that chloramines and bromamines are likely to mediate many of the effects of the parent hypohalous acids. Both are two-electron oxidants that are less reactive than their parents and more selective for sulfur centers. Chloramines can react with a further HOCl molecule to form dichloramines (RNCl_2), which are more reactive but less stable than the monochlorinated species.^{145,146}

6 TRANSITION METALS

Redox-active transition metals such as iron and copper are key participants in the biological chemistry of ROS. By donating or accepting a single electron, they both generate and remove radical species. Metalloproteins, for example peroxidases, SODs, catalases, act as pro-oxidants and antioxidants. Low molecular weight metal complexes are also important initiators of radical reactions, through Fenton-type reactions with hydrogen peroxide and as autooxidation catalysts.

6.1 Fenton Chemistry

The Fenton reaction has been much studied as a source of hydroxyl radicals and initiator of biological damage.^{94,147–149} In its simplest form, it can be written (where iron is complexed to ligand L) as

Fenton chemistry strictly involves iron and the name originates from observations by Fenton in the 1880s that a mixture of acidified iron and hydrogen peroxide generates a strong oxidant. The term *Fenton-like* is also used to describe comparable reactions of other transition metals such as copper. Over the years, there has been considerable debate as to whether the product is indeed the hydroxyl radical or a higher oxidation state of the metal (such as ferryl $[\text{FeO}]^{2+}$ or Cu(III) complexes). Product analyses and competition kinetic studies have been carried out with a variety of iron chelates and detector systems and led to differing conclusions.^{147,150,151} There is no simple answer, but the situation can be summed up as follows.^{148,152} On thermodynamic grounds, (18) is unlikely to occur as shown.¹⁵³ More likely is an inner sphere mechanism in which there is an initial formation of a ferrous peroxide (Fe(IV)) complex (reaction 19), which can convert to a ferryl species (20), breakdown to give hydroxyl radicals (equation 21), or directly oxidize a substrate (22).

In biological media, iron and copper exist as complexes either with small molecules such as citrate or ATP or bound to macromolecules. The rate of (19) varies depending on the nature of the chelator. The extent to which the initial complex undergoes (20) or (21) as against reacting directly with a substrate also depends on the chelator as well as the nature of the target. So in different circumstances, one or all three of the reactive species may act in (22) as the Fenton oxidant. This is extremely difficult, if not impossible, to distinguish kinetically. However, the initial complex and the ferryl species are both strong oxidants, so regardless of which species is involved, the products from a particular substrate are likely to be similar. Therefore, in most situations, the reactive species is best described as the Fenton oxidant.

An important variation of this reaction is where the metal is bound to a biological molecule that may itself be oxidizable, in which case, site-localized oxidation by the bound Fenton oxidant can occur. Examples of this are copper-catalyzed oxidation of DNA, and protein oxidation by an iron/ascorbate system.^{154,155}

Transition metal ions are present physiologically at low concentrations. Therefore, sustained production of Fenton oxidants requires the oxidized metal to be recycled. Although this was once thought to be an important role for superoxide, in what is commonly referred to as the superoxide-driven Fenton reaction or Haber–Weiss reaction, other reductants such as ascorbate are better able to perform this function.¹⁵⁶

Chelation or sequestration of transition metals to limit their redox activity (such as iron in transferrin or ferritin) is an important protective mechanism against oxidative damage.⁹⁴ However, these metals are in a dynamic state in cells, where low micromolar concentrations of non-protein bound iron can be measured.^{157,158} A major site of iron availability is the lysosome, where metalloproteins are degraded and the low pH enhances both its stability and reactivity.¹⁵⁹ These organelles are an important site for biological damage due to Fenton chemistry and protective effects of chelators, such as desferrioxamine, may be largely attributed to complexation of lysosomal iron.¹⁶⁰

7 KINETICS AND THE IDENTIFICATION OF BIOLOGICAL TARGETS

Each of the ROS described above has been shown to react with numerous individual biomolecules when studied in isolation. Not all of these will be relevant in a more complex biological context, as some will be outcompeted by other more reactive targets. The key factors are how fast a target reacts with the oxidant (defined by the rate constant) and its concentration. Thus, a constituent with a high rate constant may not be favored if its abundance is low. The fraction (F) of an oxidant reacting with one substrate (A) in competition with n other substrates is described by the simple kinetic expression (where k_a and k_n are the rate constants for substrates A and S_n).

$$F = k_a[A]/\Sigma k_n[S_n] \quad (23)$$

This relationship can be used to predict what reactions an oxidant is likely to undergo. It has been used to analyze reactions of nitric oxide, superoxide, and peroxynitrite under various conditions^{111,161} and to identify likely the targets for hypochlorous acid in the neutrophil phagosome and plasma.^{133,162} As described below and by Stone,¹⁶³ kinetic modeling can also identify cellular thiol proteins that are likely the targets for hydrogen peroxide.

Simple kinetic analysis also enables the effectiveness of antioxidants to be assessed. It demonstrates that realistic concentrations of ascorbate can inhibit radical reactions in plasma, but dietary polyphenolics cannot reach sufficiently high concentrations to compete with the ascorbate already present.¹⁶⁴ It also shows that it is impossible for any compound to act as an effective hydroxyl radical scavenger *in vivo*. Most compounds react with hydroxyl radicals with rate constants in the $10^9 \text{ M}^{-1} \text{ s}^{-1}$ range. So even the best scavenger, with a rate constant at the upper limit of $\sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$, could not reach a high enough concentration for its $k[\text{S}]$ to impact on the sum of $k_n[\text{S}_n]$ for all the physiological substrates present.

While kinetic analyses are valuable for identifying major oxidant targets, minor reactions should not be ignored if they impart a gain of function to the target. For example, DNA modification may in quantitative terms make a negligible contribution to the overall reactions of a radical, but by introducing a mutation to a single base, its effects could be far reaching. Alternatively, an unfavorable reaction that inhibits an enzyme by only a few percent is unlikely to have functional consequences.

7.1 Thiol Proteins as Targets for Hydrogen Peroxide

Reversible oxidation of thiol proteins is an important mechanism in cell signaling.^{14,165–167} Redox signals can be initiated by exogenous hydrogen peroxide, and in many instances receptor-mediated signaling is proposed to be due to endogenously generated hydrogen peroxide. However, there is uncertainty about which thiol proteins are directly targeted by hydrogen peroxide and how redox signals are transmitted. Kinetic modeling provides insight into potential mechanisms. Hydrogen peroxide reacts with the thiolate anion rather than the protonated

thiol, so a low $\text{p}K_a$ imparts have higher reactivity at neutral pH. Reaction rates with low molecular weight thiols decrease with increasing $\text{p}K_a$, but their thiolates all have similar rate constants ($\sim 20 \text{ M}^{-1} \text{ s}^{-1}$).¹²⁰ A minority of proteins including protein tyrosine phosphatases (PTPs) and peroxiredoxins have low $\text{p}K_a$ thiols (5–6 compared with 8.8 for GSH). Rate constants that have been measured for PTPs are similar or less than 10-fold higher than for low molecular weight thiolates¹⁶³ and few other cellular proteins have been shown to react faster.¹⁶⁷ An exception is the peroxiredoxins, which are a family of highly abundant thiol proteins that react exceptionally rapidly with hydrogen peroxide (rate constants in the 10^5 – $10^7 \text{ M}^{-1} \text{ s}^{-1}$ range).^{131,168–171}

Modeling a simple system containing these proteins, GSH, and glutathione peroxidase at estimated cell concentrations gives a clear picture (Figure 7). The peroxiredoxin and seleno-glutathione peroxidase (which has a slightly higher reactivity but lower abundance than the peroxiredoxins) trap almost all the peroxide, a tiny proportion reacts directly with GSH and the PTPs compete poorly even with GSH. Thus a low $\text{p}K_a$ is not on its own sufficient for a cellular protein to be oxidized by hydrogen peroxide and in homogeneous conditions, the low $\text{p}K_a$ PTPs and related enzymes that are widely considered as peroxide targets in cell signaling would not be competitive kinetically. The situation in a real cell, where there are thousands of proteins in different compartments, is much more complex. Although catalase is largely confined to peroxisomes, it is likely to have some role by removing hydrogen peroxide that diffuses into these organelles. For other proteins to be direct targets, it would seem that they would need to have reactivity approaching that of a peroxiredoxin. At least in mammalian cells, no other thiol proteins with this reactivity have been identified.

Oxidation of thiol proteins, including PTPs, has been observed during cell signaling.^{174,175} One possible explanation is that oxidation is indirect, and highly reactive proteins such as peroxiredoxins act as hydrogen peroxide sensors.^{127,165,166,176} Peroxiredoxins, as reviewed elsewhere,¹⁶⁸ undergo reversible oxidation to disulfides, and can be “hyperoxidized” at the active site Cys to a sulfinic acid. Their main function is usually considered to be peroxide-removal as part of the cell’s antioxidant defense,^{168,177–179} but a plausible alternative is that

Figure 7 Competition for hydrogen peroxide between typical peroxiredoxin (Prx), seleno-glutathione peroxidase (GPx), protein tyrosine phosphatase (PTP), and GSH at estimated cellular concentrations. Concentrations and rate constants used are GSH 2 mM and $0.89 \text{ M}^{-1} \text{ s}^{-1}$,¹²⁰ Prx 20 μM , $2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$,¹⁶⁹ PTP 0.1 μM , $20 \text{ M}^{-1} \text{ s}^{-1}$ (PTP1B),¹⁷² or $160 \text{ M}^{-1} \text{ s}^{-1}$ (Cdc25B).¹⁷³ Concentrations are approximations assuming a total cellular protein concentration of 250 mg/ml, average molecular weight of 25–50 kDa, so that a component that makes up 0.1% of total protein would be 5–10 μM . Note that GSH and PTP relate to right-hand axis which is 10 000 times amplified.

they trap hydrogen peroxide and transmit its oxidizing capacity to other proteins. Such a mechanism has been observed in yeast where members of the peroxiredoxin family are initially oxidized by hydrogen peroxide, then transfer oxidizing equivalents via a mixed disulfide to the transcription factor YAP1 or a stress-activated MAP kinase.^{180,181} Proteins that interact with mammalian Prx1 may do so through such a mechanism.¹⁷⁶

8 DIFFUSION AND COMPARTMENTALIZATION

Cells and tissues are not homogeneous, and an important consideration is whether an oxidant will act locally or is able to diffuse from the site of generation and act at a distance. This will depend on (i) whether it is sufficiently reactive to be consumed by substrates in the immediate vicinity and (ii) whether limited membrane permeability will restrict it to the compartment in which it is generated. Even if ROS generation is localized to a particular organelle or localized membrane site, it does not

necessarily follow that the oxidant will react at that site.

8.1 Membrane Permeability

Superoxide has low membrane permeability and only limited ability to pass through anion channels^{182–184} so its reactions are largely restricted to the compartment where it is generated. On the other hand, hydrogen peroxide can diffuse through cell membranes, and aquaporins may facilitate this transfer.¹⁸⁵ Hydrogen peroxide concentration gradients across membranes do exist, however, due to differing consumption rates on either side.¹⁸⁶ Membrane permeability of other ROS depends on charge. Peroxynitrite (pK_a 6.6) and hypochlorite (pK_a 7.5), for example, are not freely diffusible but readily permeate membranes in their protonated form.^{187,188}

An interesting conundrum is how the superoxide or hydrogen peroxide generated by NADPH oxidases exert their effect. Because they are generated on the external cell surface or within an organelle

(Figure 3b), they must traverse the membrane in order to interact with an intracellular target. This is a major restraint for superoxide. However, endosomal generation could favor reactions with targets present in the endosome.^{43,189} Hydrogen peroxide would be less constrained to a compartment such as an endosome. Even though extracellular hydrogen peroxide could enter the cell, it would also diffuse in other directions and its effects would not be localized to the generation site.

8.2 Diffusion Distances

The distance a reactive species travels before it is consumed is determined by the concentrations of available substrates and the rate constants of these reactions. It decreases as the concentration(s) of reactive substrates increase and is described by the relationship (where k_n and S_n are as described for competition kinetics, l is the distance over which the oxidant drops from an initial concentration of C_0 to C , D is its diffusion coefficient¹⁹⁰)

$$\ln C/C_0 = l/\sqrt{\Sigma k_n[S_n]}/D \quad (24)$$

D is not known for cellular milieu, but for small reactive species is estimated to be not greatly less than for aqueous solution.

This expression can be used to estimate how far a species is likely to diffuse from where it is generated in the presence of particular substrate(s) and to assess whether site-localized action could occur within a cell. GSH is typically present in cells at millimolar concentrations and reacts with most radicals and two-electron oxidants. A comparison of how far various oxidants can diffuse in the presence of 2-mM GSH (Figure 8) shows that reactive radicals and non-radical species such as hypochlorous acid are restricted to act locally, but hydrogen peroxide and peroxynitrite are able to diffuse beyond the dimensions of a typical 10–20 μm diameter cell.²⁵

Diffusion of hydrogen peroxide in the presence of other potential cellular targets can also be modeled. Peroxiredoxins at typical cell concentrations of 10–50 μM are reactive and abundant enough to limit its range between 50% and 10% of the cell diameter. Glutathione peroxidases are less abundant but their high reactivity would restrict the peroxide to a similar range. Other thiol proteins such as PTPs would not restrict diffusion to within the diameter of the cell and therefore should not undergo selective oxidation at the site of peroxide generation. This analysis does not therefore support the proposal that site-localized oxidation of other thiol proteins could occur if peroxiredoxins were inactivated.^{177,179,193} An association between oxidant generator and target that facilitates transfer of the oxidant or

Figure 8 Estimated diffusion distances of selected oxidants in the presence of a nominal cellular GSH concentration of 2 mM, relative to the diameter of a generic cell (20 μm). The cell is scaled down 10-fold from left to right to illustrate that distances for peroxynitrite and hydrogen peroxide are greater than its diameter. The distance over which the oxidant concentration drops to a tenth has been taken as its diffusion distance. Rate constants ($\text{M}^{-1} \text{s}^{-1}$) for each oxidant reacting with GSH are 3×10^7 for NO_2 ¹⁹¹; 700 for peroxynitrite¹²⁴; 3×10^7 for hypochlorous acid¹²¹; 1×10^{10} for hydroxyl radicals.¹⁹² [Reproduced from Ref. 25. © Nature Publishing Group, 2008.]

confinement to a compartment that excludes other reactive substrates would be needed for this to occur.

9 FREE RADICAL SCAVENGING AND ANTIOXIDANT DEFENSE

In a biological context, an antioxidant is defined as a substance that delays, prevents, or removes oxidative modification to a target molecule.¹ Antioxidant activity is not a generic property of a substance, but will depend on context and what particular oxidant is responsible for the process under study. For example, many compounds (e.g., polyphenols, vitamin E) are excellent radical scavengers but react poorly with two-electron oxidants. Most commonly used “antioxidants” are ineffective scavengers of hydrogen peroxide. If a reaction is inhibited by *N*-acetylcysteine, for example, this would indicate that it is not directly mediated by hydrogen peroxide.

A scavenging reaction is protective only if the product is less reactive or damaging than the initial species. This is not always the case with radical reactions where scavenging of one radical generates another. Vitamin E is a good lipophilic antioxidant because the tocopheroxyl radical has low reactivity and can be removed by radical–radical reactions. However, in lipoprotein particles where opportunities for recombination are limited, it promotes lipid peroxidation (tocopherol-mediated peroxidation¹⁹⁴) unless it is scavenged by a secondary antioxidant such as ascorbate.

The main physiological radical-scavenging antioxidants in the aqueous phase are ascorbate and GSH. Ascorbate is effective because it reacts with a wide spectrum of radicals to generate ascorbyl radicals, and these disproportionate in preference to undergoing other reactions. As discussed in Section 5.1.3, radical scavenging by GSH and other thiols is effective only because cells have an efficient mechanism for removing oxidizing and potentially damaging thiyl radicals. Comparing ascorbate and GSH, the lower reduction potential of ascorbate makes it the better one-electron reductant. Ascorbate can also intercept thiyl radicals,¹¹⁵ and in cells has been predicted to play the major role.¹¹⁷ Synergy has been seen between ascorbate acting as the main scavenger and GSH recycling the dehydroascorbate formed.¹⁹⁵ In cultured cells,

which contain little or no ascorbate, scavenging by thiols should be more dominant and redox reactions could be different from in ascorbate-replete tissues.

Synergism is equally relevant for dietary or pharmacological antioxidants. Even though compounds such as polyphenolics and carotenoids are good radical scavengers, dietary intake is unable to increase tissue concentrations sufficiently to impact on total radical-scavenging capacity.¹⁶⁴ To act as radical-scavenging antioxidants (and it should be noted that this mode of action is debatable), they would need to accumulate at a site of radical generation, or act synergistically to facilitate radical transfer to more abundant species such as ascorbate or GSH.

10 CONCLUSIONS: A CONTINUUM OF BIOLOGICAL DAMAGE, OXIDATIVE STRESS, AND REDOX REGULATION

From the early days of radiation chemistry, it was realized that free radicals and other ROS are capable of damaging and killing living organisms. Many deleterious reactions with biological molecules have been characterized. Numerous chemicals generate radicals as a result of metabolic activation, and release of superoxide and hydrogen peroxide by the mitochondrial electron transport can cause oxidative stress to the cell. In some cases, free radical generation has been linked to toxicity. Animals and plants also produce ROS to combat invading pathogens. However, many cells generate superoxide or hydrogen peroxide not as toxins but for the purpose of cell signaling or metabolic regulation.

So instead of the original view that ROS are strictly damaging and antioxidants are required to protect against this damage, it is now appreciated that there is a continuum of oxidative damage, oxidative stress, and redox regulation. Clearly, certain reactive oxidants can be directly damaging or cytotoxic. However, lesser damage or exposure to less reactive species can activate stress responses. The ultimate result may still be cell death, for example by apoptosis, but the response may also upregulate expression of proteins involved in protective pathways such as antioxidant activity, DNA repair, xenobiotic detoxification, and chaperone activity. At the other end of the spectrum,

ROS can regulate the activity of oxidant-sensitive enzymes involved in cell metabolism, growth, and development. In this context, antioxidants, including enzymes such as SODs or glutathione peroxidases, need to be considered as regulators of this redox activity and not strictly for ROS removal.

There is still much to be discovered about how different responses to ROS integrate. It is simplistic to think just in terms of overall ROS exposure and we need to know what particular species are being generated in any situation, how much, and where the oxidants are located. It is also important to know what specific reactions are responsible for oxidative damage, stress responses, and redox regulation. There is extensive information available on the biomolecular modifications caused by individual oxidants, but which of these should be considered as direct damage and which as initiators of stress responses is not so clear-cut. Some stress response mechanisms are well characterized, such as the activation of the bacterial transcription factors oxyR and SoxS by hydrogen peroxide and superoxide, respectively.⁹⁹ Although information is still lacking on the molecular sites of oxidation, activation of the transcription factor Nrf2 by various oxidants and electrophiles is well established as a mechanism for upregulating protective proteins.¹⁹⁶ However, there are still large gaps in our knowledge of the oxidant-sensitive targets that initiate cell signaling responses, which oxidants they respond to, and how NADPH oxidase activation links into signaling pathways.

Location and quantification are important considerations for understanding how endogenously generated ROS act in cells or tissues. Reliable data are critically needed on how much superoxide or hydrogen peroxide is released by mitochondria, NADPH oxidases, and other enzyme systems. Development of methods that can provide this information is a high priority. Although site-localized production of ROS within cells clearly occurs, there are few cases where it has been established that the oxidant also act locally.⁴⁴ There are also unanswered questions regarding how a cell that is apparently generating significant amounts of hydrogen peroxide in the peroxisomes or the ER can respond to what would be expected to be more modest generation generated during signal transmission. These questions are starting to be addressed with the development of specific

oxidant-sensitive probes and detection methods that can follow events in live cells,^{197–199} and through characterizing the reactions that specific radicals and non-radical oxidants undergo in complex biological situations.

ACKNOWLEDGMENTS

Grant support for the author's work has come primarily from the Health Research Council of New Zealand and the Marsden Fund. I am grateful to Tony Kettle and Peter Nagy for helpful comments on the manuscript and to Kerry Winterbourn for preparing some of the figures.

Fundamentals of Controlled/Living Radical Polymerization

Krzysztof Matyjaszewski

Department of Chemistry, Carnegie Mellon University, Pittsburgh, PA, USA

1 INTRODUCTION

Commercial success of radical polymerization (RP) originates in minimal requirements for purification of monomers and solvents, convenient reaction conditions employed (typically room temperature to 100 °C, ambient pressure), large range of radically polymerizable monomers, and their facile copolymerization. Approximately 50% of all synthetic polymers are currently made via RP processes. The range of monomers is larger than that for any other chain polymerization because radicals are tolerant to many functionalities, including acidic, hydroxy, and amino groups. RP is not affected by water and protic impurities and can be carried out in bulk, solution, aqueous suspension, emulsion, dispersion, and so on. In conventional RP, high molecular weight (MW) polymers are formed at early stages of the polymerization, and neither long reaction times nor high conversions are required, in sharp contrast to step-growth polymerization.

However, RP has some limitations, especially in comparison with ionic processes that provide facile routes to living polymers. For a polymerization to be considered “living,” the contribution of chain breaking reactions such as termination and transfer should be negligible. Although transfer is not a major issue in RP when the appropriate conditions are applied, termination is much more difficult to be avoided and is a major limitation of

RP. In contrast to ionic reactions, in which cations or anions do not react via bimolecular termination, radicals terminate with a diffusion-controlled rate. In order to form high MW polymers, the relative probability of such termination must be minimized. This is accomplished by running RP at very low concentrations (from ppb to ppm) of propagating radicals. The concentrations of growing species are thus much lower in RP than in carbanionic or ring-opening polymerizations. In RP, a steady concentration of radicals is established by balancing the rate of termination with that of initiation. The rate of propagation is much faster than the rate of initiation/termination (as required to keep radical concentration low). Therefore, chains are continuously generated and it is not possible to prepare (co)polymers with controlled architecture by conventional RP. As discussed in other articles (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications and Kinetics of Polymerizations**), in RP, a propagating radical reacts with monomer approximately every 1 ms and chains typically terminate after ≈ 1 s, during which time high MW polymer is formed (degree of polymerization (DP) ≈ 1000). At any given moment of the polymerization, the number of growing chains which can be functionalized or chain-extended is very small (i.e., $<0.1\%$), unlike in ionic living polymerization, which is essentially carried out with instantaneous initiation and without chain breaking reactions.

Thus, it has not been possible to prepare well-defined (co)polymers via conventional RP. However, new approaches that exploit equilibria between growing radicals and dormant species have been recently developed to minimize the proportion of terminated chains in RP. Such controlled RPs with reversible deactivation (controlled/living radical polymerization (CRP), IUPAC recommends the term *controlled reversible-deactivation radical polymerization*) are mechanistically similar to conventional RP methods and proceed through the same reactive intermediates. However, the proportion of terminated chains in CRP is dramatically reduced from >99.9% to circa less than 10% and sometimes even less than 1%. Since termination cannot be entirely avoided in CRP, these systems are never living at a level of anionic polymerization. However, the degree of control is often sufficient to attain many desirable material properties.

In this article, the fundamentals of controlled RP are first summarized and followed by the brief description of stable free radical polymerization (SFRP), atom transfer radical polymerization (ATRP), and reversible addition–fragmentation transfer (RAFT), as an example of degenerative transfer (DT) processes. All CRP systems enable the synthesis of many well-defined copolymers with novel architectures, compositions, and functionalities. These features and some possible applications of these materials are not discussed here, as they are covered in detail in articles devoted to particular polymerization methods (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**, **Nitroxide-Mediated Polymerization and its Applications**, **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**, and **Sb, Bi, Te, and I-Transfer Polymerization and Applications**).

2 CONTROLLED REVERSIBLE-DEACTIVATION RADICAL POLYMERIZATION

2.1 General Concepts

Controlled synthesis of polymeric materials requires minimization of chain breaking reactions and simultaneous growth of all chains. A prerequisite

Scheme 1

Scheme 2

of fast initiation and very slow termination seems to disagree with the fundamental principles of RP, in which steady state of radical concentration is achieved by equal rates of initiation and termination. However, such a scenario was realized by the development of controlled/“living” systems in which the active propagating radicals are intermittently formed. This concept, originally applied to cationic ring-opening polymerization,¹ was later successfully extended to carbocationic systems.²

A dynamic equilibrium between propagating radicals and various dormant species is the most important feature of all CRP systems.^{3,4} There are two types of equilibria. Radicals may be reversibly trapped in a deactivation/activation process, according to Scheme 1 or they can be involved in a degenerative exchange process (Scheme 2).

The first approach is more widely used and relies on the persistent radical effect (PRE).^{5,6} In systems obeying the PRE, newly generated radicals are rapidly trapped in a deactivation process (with a rate constant of deactivation, k_{da}) by species X (which is typically a stable radical such as a nitroxide^{7,8} or an organometallic species such as a cobalt porphyrine^{9,10}). The dormant species are activated (with a rate constant k_a) either spontaneously/thermally, in the presence of light, or with an appropriate catalyst (as in ATRP)^{11,12} to reform the growing centers. Radicals can propagate (k_p) and also terminate (k_t). However, persistent radicals (X) cannot terminate with each other but only (reversibly) cross-couple with the growing species (k_{da}). Thus, every act of termination between growing radicals is accompanied by the irreversible accumulation of X. Its concentration

progressively increases with time, following a peculiar one-third power law.^{4–6} The growing radicals then predominantly react with X, which is present at >1000 times higher concentration, rather than with themselves. As the concentration of X increases with time, the concentration of radicals decreases (as the equilibrium in Scheme 1 becomes shifted toward the dormant species) and the probability of termination is diminished.

In systems based on the PRE, a steady state of growing radicals is established through the activation–deactivation process but *not* through initiation–termination. Because initiation can be much faster than termination, it essentially gives rise to the simultaneous growth of all chains. In contrast, systems that employ DT are *not* based on the PRE. They follow typical RP kinetics with slow and continuous radical supply (e.g., with the rate constant of decomposition of thermal initiator, k_d) and termination (k_t). The transfer agent is at much larger concentration than radical initiator and thus formally plays the role of a dormant species.

Good control over MW, polydispersity, and chain architecture in all CRP systems requires fast exchange between active and dormant species. Ideally, a growing radical should react with only a few monomer units before it is converted back into a dormant species. Consequently, it would remain active only for a few milliseconds and would return to the dormant state for a few seconds or longer. The growth of a polymer chain may consist, for example, of ~1000 periods of ~1-ms activity, interrupted by ~1000 periods of ~1-min dormant states. The lifetime in the active state is thus comparable to the lifetime of a propagating chain in conventional RP (~1000 ms, i.e., ~1 s). However, because the entire propagation process in CRP may take ~1000 min or ~1 d, this facilitates various synthetic procedures, such as functionalization or chain extension, block copolymerization, and so on. Also, simultaneous growth of all chains enables multidirectional growth of chains and preparation of stars, combs, molecular brushes, and other complex architectures.¹³

2.2 Similarities and Differences between RP and CRP

Since RP and CRP proceed via the same radical mechanism, they exhibit similar chemo-, regio-, and

stereo-selectivities and can polymerize a similar range of monomers. If RP and CRP are carried out with the same rate, the absolute amount (concentration) of terminated chains is similar (not exactly the same, due to chain length-dependent termination (CLDT)), because concentrations of radicals are similar. However, in RP, essentially all chains are dead, but in CRP, dead chains form only a small fraction (<10% of all chains) due to a large amount of dormant species. Nevertheless, several important differences between CRP and RP exist and are summarized below.

1. The lifetime of growing chains is extended from ~1 s in RP to more than 1 h in CRP. This is done by the involvement of dormant species and intermittent reversible activation.
2. In RP, a steady-state radical concentration is established with similar rates of initiation and termination, whereas in CRP systems based on the PRE (ATRP and SFRP), a steady radical concentration is reached by balancing the rates of activation and deactivation.
3. In conventional RP, initiation is slow and a relatively large fraction of free radical initiator is often left unconsumed at the end of the polymerization. In most CRP systems, initiation is fast and all chains start growing at essentially the same time, ultimately enabling control over chain architecture.
4. In RP, nearly all chains are dead, whereas in CRP, the proportion of dead chains is usually <10%.
5. Polymerization in CRP is often slower than in RP, but this does not necessarily have to be the case. Rates may be comparable, especially if the targeted MW in CRP is relatively small.
6. In conventional RP, termination predominantly occurs between long chains and constantly generated new chains. In CRP systems based on the PRE (ATRP and SFRP), at the early stages, all chains are short (most probable termination), but as they become much longer, the termination rate significantly decreases. In DT processes (e.g., RAFT), new chains are constantly generated by a small amount of conventional initiator, and therefore, termination is more likely.
7. There are also several degrees of control molecular architecture unique for CRP. This includes preparation of polymers with predetermined

MW and designed MW distribution and complex architectures.

8. Use of multifunctional initiators provides new avenues to concurrent and multidirectional growth of polymer chains in CRP, resulting in well-defined star, graft, or even brush macromolecules. These special features enable formation of many hybrid materials. Such architectures are not available from RP.
9. Copolymerization of comonomers with different reactivity ratios results in mixture of copolymers with different composition due to continuous drift in comonomer feed in RP. In CRP, the same copolymerization results in novel gradient copolymers with essentially identical structure among all chains.
10. Chain capping agents from dormant species in CRP can be used for subsequent functionalization and formation of heterotelechelic or homotelechelic polymers. In CRP, end functionalities can be incorporated only via transfer reactions.

3 HOW FAST CAN A CRP BE CONDUCTED WITH PRESERVED CHAIN END FUNCTIONALITY?

Faster RP requires higher concentration of radicals, which in turn results in more pronounced termination. Therefore, chain end functionality (CEF) and control are progressively lost at higher polymerization rate in any CRP. Nevertheless, there is some confusion about how fast can any CRP be with sufficiently preserved CEF? Can we have ultrafast polymerization leading to ultrahigh MW and with preserved "livingness"? Which are the most important parameters that influence fraction of dead chains versus polymerization rate to the largest extent? Does this fraction depend on the mechanism of polymerization (e.g., ATRP vs RAFT)? Kinetic modeling will help to answer these questions.

Independently of the mechanism of exchange between active and dormant species, propagation and termination steps are the same in any RP. The rate of propagation (R_p) is proportional to the propagation rate constant (k_p), the concentrations of monomer ($[M]$), and propagating radical ($[R^*]$) as

expressed in (1), where t is the polymerization time:

$$R_p = -\frac{d[M]}{dt} = k_p[M][R^*] \quad (1)$$

According to (1), for the same monomer, faster polymerization requires higher $[R^*]$. However, increased radical concentration also results in faster bimolecular termination:

$$R_t = \frac{d[T]}{dt} = 2k_t[R^*]^2 \quad (2)$$

where k_t is the termination rate constant and $[T]$ is the concentration of the dead chains resulting from radical termination. Thus, the unavoidable penalty for faster polymerization (i.e., higher radical concentration) is progressively higher proportion of terminated chains and loss of livingness. Nevertheless, very fast CRPs with preserved control or functionality have been claimed in literature.^{14,15} The fraction of extendable chains is defined by preserved CEF. Consequently, for any CRP a minimal time is required to preserve a specific value of CEF. This time primarily depends on the type of monomer (propagation rate constant and termination rate constant), targeted DP (DP_T), initial monomer concentration, and targeted monomer conversion.

Retention of CEF is needed for synthesis of various telechelic polymers, segmented copolymers, and, especially, block copolymers.

3.1 Dead Chain Fraction in CRP

In CRP systems, linear first-order kinetic plots are often observed, indicating constant radical concentration, due to either steady state by equal rates of initiation and termination (DT systems) or balanced rates of activation and deactivation and negligible termination for PRE systems. At constant $[R^*]$, the integration of (1) gives the relationship between polymerization time (t), monomer conversion (p), and $[R^*]$:

$$\ln(1 - p) = -k_p[R^*]t \quad (3)$$

The concentration of terminated chains can be calculated by the integration of (2):

$$[T] = 2k_t[R^*]^2t \quad (4)$$

The combination of (3) and (4) yields the concentration of terminated chains as a function of time and conversion:

$$[T] = \frac{2k_t[\ln(1-p)]^2}{k_p^2 t} \quad (5)$$

The DP_T is defined as the ratio of initial monomer concentration, $[M]_0$, to the concentration of living polymers, $[P-X]$ (equal to initiator concentration, $[R-X]_0$, for quantitative initiation). Hence, the dead chain fraction (DCF) can be expressed by the following equation:

$$DCF = \frac{[T]}{[R-X]_0} = \frac{2DP_T k_t [\ln(1-p)]^2}{[M]_0 k_p^2 t} \quad (6)$$

To simplify calculations, the decrease in the number of chains by bimolecular combination (corresponding to quantitative disproportionation) is neglected. Thus, the DCF defines the fraction of living chains lost from the initial living chains. Knowing DCF, one can calculate the CEF by the following equation:

$$CEF = 1 - DCF \quad (7)$$

Equation (6) indicates that there are several potential strategies that can be employed to decrease the fraction of dead chains: reducing the rate of polymerization (larger t), quenching the reaction at lower monomer conversion (smaller p), targeting lower DP_T , using higher initial monomer concentration (larger $[M]_0$), or choosing monomers with an inherently lower value of $k_t/(k_p)^2$. In the following discussion, we will individually discuss all parameters involved in (6) and determine how they influence CEF.

3.2 Minimal Polymerization Time in CRP

Since (6) includes six parameters, it is convenient to fix some parameters and test how the remaining one or two parameters affect the DCF. For example, in the bulk polymerization of methyl methacrylate (MMA) at 80 °C ($k_t = 9.00 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, $k_p = 1300 \text{ M}^{-1} \text{ s}^{-1}$, and $[M]_0 = 9.34 \text{ M}$) the effect of polymerization time, monomer conversion, and DP_T on DCF can be correlated. DCF is inversely

proportional to polymerization time when targeting a certain DP_T and a specific degree of conversion:

$$DCF = C_1 t^{-1}, C_1 = \frac{2DP_T k_t [\ln(1-p)]^2}{[M]_0 k_p^2} \quad (8)$$

In (8), C_1 is a constant when every parameter except t is fixed. Figure 1 illustrates the relationship of DCF and the polymerization rate in two ways. In Figure 1a, three different DP_T s are targeted at 60% conversion, while Figure 1b illustrates effect of different degrees of conversion for a targeted $DP_T = 500$. Both procedures show a similar trend that a reduced fraction of dead chains, or increased livingness, can be achieved by slowing down the polymerization. Both higher DP_T and higher conversion give larger value for C_1 . However, curves for higher DP_T or higher conversion give steeper slope than the lower values. For example, in Figure 1a, the DCF decreased with polymerization time and this decrease was the most significant for $DP_T = 1000$. Figure 1a shows that targeting $DP_T = 1000$ at 60% conversion in 15 h leads to 18% of dead chains ($CEF = 82\%$). Also, to preserve 95% of chains at 60% conversion while targeting poly(methyl methacrylate) (PMMA) with $DP_T = 500$ requires 27 h. In addition, for $DP_T = 500$ and conversion 80%, reaction performed within 15 h leads to 27% of dead chains.

3.3 Influence of Conversion on DCF

DCF is also affected by conversion as shown by the following equation:

$$DCF = C_2 [\ln(1-p)]^2, C_2 = \frac{2DP_T k_t}{[M]_0 k_p^2 t} \quad (9)$$

Polymerization targeting a certain DP_T will lose more living chains when achieving higher conversion within the same time. Figure 2 illustrates this in two ways, using again MMA bulk polymerization at 80 °C, as an example. According to Figure 2, targeting 70% conversion in 40 h leads to 6% of dead chains for $DP_T = 500$. For $DP_T = 1000$ with 30-h targeted polymerization time, the reaction only loses 5% of living chains at 50% conversion.

Figure 1 Plots of DCF versus polymerization time for bulk polymerization of MMA at 80 °C. (a) Three different DP_T s at 60% conversion and (b) three different conversions for $DP_T = 500$. [Reprinted with permission from Ref. 14. American Chemical Society.]

Figure 2 Plots of DCF versus conversion for bulk polymerization of MMA at 80 °C. (a) Three different rates of polymerization for $DP_T = 500$ and (b) three different DP_T values in 30 h. [Reprinted with permission from Ref. 14. American Chemical Society.]

3.4 Influence of DP_T on DCF

To retain the same CEF at the same conversion, the systems with higher DP_T require slower rate of polymerization. The relationship between DCF and DP_T (10) for bulk polymerization of MMA at 80 °C is illustrated in Figure 3. The linear slopes decrease with polymerization time but increase

with conversion. Figure 3a shows that 89% CEF can be preserved when targeting $DP_T = 800$ and achieving 60% conversion within 20 h. Reaching 80% conversion within 30 h results in 16% of dead chains when targeting $DP_T = 600$:

$$DCF = C_3 \times DP_T, C_3 = \frac{2k_t[\ln(1-p)]^2}{[M]_0 k_p^2 t} \quad (10)$$

Figure 3 Plots of DCF versus DP_T for bulk polymerization of MMA at 80 °C. (a) Three different rates of polymerization at 60% conversion and (b) three different conversions reached in 30 h. [Reprinted with permission from Ref. 14. American Chemical Society.]

3.5 Preparation of Polymers with a Specific DP

A polymer with the same specific DP can be prepared by targeting higher DP_T at lower conversion or targeting lower DP_T at higher conversion. Which approach provides lower DCF within the same time? Both higher DP_T and higher conversion lead to more dead chains at the same polymerization rate. Since DP can be expressed as the product of DP_T and conversion, that is, $DP = DP_T \times p$, (6) converts to

$$DCF = \frac{2DP_T k_t}{[M]_0 k_p^2 t} \frac{[\ln(1-p)]^2}{p} \quad (11)$$

In (11), the second term of the product ($[\ln(1-p)]^2/p$) is an increasing function of p . Since the first term in the equation contains two rate constants and three fixed values, it remains constant and DCF increases with p . Hence, the combination of higher DP_T and lower conversion gives less dead chains when targeting a certain polymer DP within the same polymerization time.

Figure 4 shows an example of the DCF formed during formation of PMMA with different DPs. In this plot, every point on the three-dimensional surface stands for one polymerization reaction stopped within 5 h. In three curves, the product of conversion and DP_T is a fixed value. Along the

same curve, the desired DP does not change, while the trend of DCF obeys the above conclusion. For instance, to synthesize PMMA with $DP = 60$, one could target $DP_T = 75, 100$, and 150 , but stop the reaction at 80, 60, and 40% conversion, respectively. Based on the data in Figure 4, those three systems will generate polymers with DCF = 12.3, 5.3, and 2.3%, respectively. Thus, synthesis of $DP_T = 150$ at 40% conversion gives five times lower DCF than aiming at $DP_T = 75$ at 80% conversion in preparation of PMMA with $DP = 60$.

3.6 Influence of Initial Monomer Concentration on DCF

Previous example showed that polymerization diluted by monomer is better controlled. Can dilution by solvent also provide better control? The addition of a solvent may sometimes be necessary to improve the solubility of the polymer or catalyst or to control the viscosity of the system. The role of the solvent is not the same as that of the monomer and (12) shows that solvent is not a good diluent for decreasing DCF because it actually reduces $[M]_0$, correspondingly increasing DCF:

$$DCF = \frac{C_4}{[M]_0}, C_4 = \frac{2DP_T k_t [\ln(1-p)]^2}{k_p^2 t} \quad (12)$$

Figure 4 Plot of logarithmic value of DCF versus conversion and DP_T for PMMA for three different desired DPs. Conditions: 80 °C, bulk polymerization, 5 h. [Reprinted with permission from Ref. 14. American Chemical Society.]

In comparison with bulk polymerization, when the monomer is diluted by solvent, the radical concentration must increase in order to maintain the same polymerization rate. This causes more termination at the same rate of polymerization. Figure 5 shows the DCF after 10 h for a MMA polymerization conducted at 80 °C targeting $DP_T = 500$. At the same conversion, bulk polymerization always gives a lower DCF. Selecting the point at 70% conversion from each of these three curves, bulk polymerization generates only 7.7% of dead chains, while the other two DCFs are 11.5 and 15.3%, respectively.

3.7 Effect of k_t and k_p Values on DCF and Minimal Polymerization Time

The above conclusions are universal for any CRP. Higher CEF requires slower polymerization, higher monomer concentration, lower DP_T , and stopping polymerization at lower conversion. However, the relationship between “how fast” and “how living” a CRP is, strongly depends on the polymerized monomers and more specifically on k_p and k_t values. Equation (13) shows that lower $k_t/(k_p)^2$ value gives less dead chains under specific condition (constant C_5), thus low k_t and high k_p are both desired:

$$DCF = C_5 \frac{k_t}{k_p^2}, \quad C_5 = \frac{2DP_T[\ln(1-p)]^2}{[M]_0 t} \quad (13)$$

Figure 5 Comparison of DCFs for three different initial monomer concentrations. Conditions: 80 °C, $[MMA]_0/[R-X]_0 = 500/1$, 10 h. [Reprinted with permission from Ref. 14. American Chemical Society.]

In RP, termination is often a diffusion-controlled process and difference between termination rate constants for various monomers is not large, although it depends on chain length and conversion. However, propagation rate constants depend strongly on monomer structure. For example, at 80 °C, the k_p of styrene (St) is circa twice smaller than that of MMA but nearly two orders of magnitude smaller than that of methyl acrylate (MA). Table 1 shows corresponding rate constants and values for 90% preservation of CEF for these three

Table 1 Minimal time for the polymerization of MA, MMA, and St with CEF = 90%.^a

Monomer	k_p (M ⁻¹ s ⁻¹) ^b	k_t (M ⁻¹ s ⁻¹) ^b	DP _T = 500		DP _T = 100	
			$p = 60\%$	$p = 90\%$	$p = 60\%$	$p = 90\%$
MA	47 400	1.10×10^8	37 s	4 min	7 s	1 min
MMA	1 300	9.00×10^7	13.3 h	83.9 h	2.7 h	16.8 h
St	665	1.10×10^8	2.8 d	17.5 d	0.6 d	3.5 d

^a Conditions: 80 °C, [M]₀/[R-X]₀ = DP_T/1, bulk polymerization.^b k_p and k_t values were obtained or estimated from the literature.^{16–20} k_t value is the sum of k_{tc} (the combination rate constant) and k_{td} (the disproportionation rate constant).**Figure 6** Contour maps for DCF as a function of conversion and polymerization time for different monomers. (a) MA, (b) MMA, and (c) St Conditions: 80 °C, [M]₀/[R-X]₀ = 500/1, bulk polymerization. Scale bar represents the logarithmic value of DCF.

monomers. Three “contour maps” are plotted in Figure 6 for the bulk polymerization of MA, MMA, and St, targeting the same DP_T = 500 at 80 °C. Each contour corresponds to the logarithmic value of DCF and three solid lines show the relationship between reaction time and conversion for DCF = 5, 10, and 30%. For example, it is possible to prepare poly(methyl acrylate) (PMA) with 90% preserved CEF for DP_T = 500 at 60% conversion in 37 s. However, as highlighted by bold entries in Table 1, the same control requires 13 h for PMMA and 2.8 d for polystyrene (PS)! The other entries show the effect of DP_T for 500 and 100 values for PMA at 90% conversion. The former requires 50 min but the latter only less than 1 min. Finally, the other entries show that the same CEF = 90% for PS and DP_T = 100 requires 3.5 d at 90% but only 0.6 d at 60% conversion.

3.8 Evaluation by CLDT

The “maps” shown in the figures were constructed for constant values of termination rate coefficients.

However, since termination is diffusion limited, it depends on viscosity and chain length. Thus, the CLDT rate coefficients strongly depend on both conversion and DP.²⁰ The effect of CLDT rate coefficient was analyzed as a function of DP and conversion for bulk polymerization of MMA and MA at 80 °C.^{21,22} Figure 7 provides a more accurate evaluation of DCF of PMMA by integrating the CLDT data. The system with DP_T = 500 (Figure 7a) does not show a significant difference compared to the non-CLDT evaluation. However, in the DP_T = 5000 system (Figure 7b), the curves for specific DCFs display a dramatic drop in termination reactions, which means that much faster polymerization can be conducted for a system with a high DP_T. For example, to preserve 90% CEF at 50% conversion targeting PMMA with DP_T = 5000, it requires 40 h, which is nearly twice shorter time than that predicted by non-CLDT.

Although the required rate of polymerization for acceptable CEF depends on the type of monomer, there are some other possibilities of decrease $k_t/(k_p)^2$ via tuning various reaction conditions. For example, an increase in temperature results in an

Figure 7 Plots comparing DCF of PMMA computed with and without CLDT. (a) $DP_T = 500$ and (b) $DP_T = 5000$. Conditions: 80°C , $[M]_0/[R-X]_0 = 500/1$, bulk polymerization. Scale bar represents the logarithmic value of DCF. [Reprinted with permission from Ref. 14. American Chemical Society.]

increase in the polymerization rate without a significant loss of CEF since higher temperature increases k_p much more than k_t , due to lower activation energy of termination compared to that of propagation. However, there is a limit in temperature increase due to chain transfer (e.g., acrylates), self-initiation (e.g., St), and depropagation (e.g., methacrylates). Pressure is another important parameter.²³ Radical propagation has a negative volume of activation, while termination has a positive one and higher pressure not only enhances k_p but also reduces k_t . This strategy has been successfully applied to synthesize high MW polymers by activators generated by electron transfer (AGET) ATRP²⁴ and RAFT polymerization.^{25–28}

3.9 CEF in CRP Systems Involving Extra Radical Initiators

There are several CRP processes relying on DT mechanism, such as RAFT polymerization, that employs radical initiators (e.g., azobisisobutyronitrile (AIBN)). To this category also belong the initiators for continuous activator regeneration (ICAR) ATRP. The radical initiators continuously generate new chains. Thus, there are two populations of living chains, those generated from the original (macro)initiator R-X and newly generated, also

extendable chains I-X and I-P-X. The R group may play an important role. It can be the first block in a block copolymer, and it can represent a surface in surface-initiated CRP, natural product in bioconjugates, or a specific functionality in telechelics. Thus, although I-X and I-P-X species can grow, they will not contain an important R moiety. Therefore, it is useful to define two types of CEF in the systems involving radical initiators. The first definition is similar to the general case for CRP, which is the fraction of all extendable chains (P-X), and the second one describes the fraction of chains with dual functionality (R-P-X). Since extendable species include initiator and living polymer, to simplify the following discussion, we define [R-P-X] as the total concentration of dual functionalized chains, including R-P-X chains and original initiator R-X. Similarly, [I-P-X] contains I-P-X chains and newly generated initiator I-X. Thus, [P-X] is the sum of [R-P-X] and [I-P-X].

Since ICAR ATRP and other DT processes (as RAFT polymerization) follow similar kinetics, the results provide more general conclusions for all DT systems. ICAR ATRP (or RAFT) is accelerated in the presence of increased concentration of radical initiators. However, although such systems, also named as hybrid ATRP¹⁵, result in faster polymerization, they also result in a larger loss of CEF. The number of polymer chains with dual

Figure 8 Plots of DCF in ICAR ATRP. (a) Fraction of termination chains, (b) fraction of α -I group-terminated extendable chains, and (c) fraction of all dead chains. Conditions: 60 °C, $[St]_0/[EtBrIB]_0/[CuBr_2]_0/[TPMA]_0/[AIBN]_0 = 200/1/0.01/0.01/x$ ($x = 0.05, 0.10, 0.15$), $St/acetoneitrile = 2/1$ (v/v) ($R-X = EtBrIB$). [Reprinted with permission from Ref. 14. American Chemical Society.]

α , ω -functionality drops significantly with increased radical initiator concentration.

$[T]$ is still defined as the concentration of terminated chains, including those forming between two polymeric radicals, between one polymeric radical and one initiator radical ($I^{\bullet}$ or $R^{\bullet}$). $[D]$ is defined as the concentration of all types of dead chains, including nonextendable chains and those extendable chains possessing an α -I group. Thus, a new definition for DCF is expressed by the following equation:

$$DCF = \frac{[D]}{[\text{All chains}]} = \frac{[T] + [I-P-X]}{[\text{All chains}]} \quad (14)$$

In ICAR and RAFT systems, the number of extendable chains does not change, since lost $R-X$ and $R-P-X$ chains are replenished by $I-X$ and $I-P-X$

chains. Figure 8a and b shows the fractions of terminated chains and α -I group-terminated extendable chains. The increase in $[AIBN]_0$ increases all types of dead chains (all chains except $R-X$ and $R-P-X$ ones), as illustrated in Figure 8c. Thus, although formally, concentration of extendable chains does not change, with 15% AIBN, there are already 9% of terminated chains at 50% conversion and also only 76% of chains with dual-CEF left!

The difference in CEF between CRP with and without radical initiator can be compared using ICAR ATRP and normal ATRP. In order to provide a fair comparison, specific conditions were chosen for these two polymerizations to proceed at a similar rate. Under these conditions, the differently defined CEF values are shown in Figure 9. The CEF in Figure 9a is defined as the fraction of extendable chains among initial living chains. For normal

Figure 9 Comparison of CEFs in ICAR ATRP, and normal ATRP according to different CEF definitions. (a) Fraction of extendable chains among initial living chains (initiator), (b) fraction of dually functionalized chains among initial living chains, (c) fraction of extendable chains among all chains, and (d) fraction of dually functionalized chains among all chains. Conditions: ICAR ATRP, 60 °C, $[St]_0/[EtBrB]_0/[CuBr_2]_0/[TPMA]_0/[AIBN]_0 = 200/1/0.01/0.01/0.05$, $St/acetoneitrile = 2/1$ (v/v); normal ATRP, 60 °C, $[St]_0/[EtBrB]_0/[CuBr]_0/[CuBr_2]_0/[PMDTA]_0 = 200/1/0.945/0.055/1$, $St/acetoneitrile = 2/1$ (v/v) (PMDTA: N,N,N',N'',N'' -pentamethyldiethylenetriamine; R-X = EtBrB). [Reprinted with permission from Ref. 14. American Chemical Society.]

ATRP, the concentration of extendable chains decreases due to unavoidable termination reactions, leading to the accumulation of persistent radicals (CuX_2/L). However, according to the conservation of X groups and steady state in ICAR ATRP, every lost X through termination is replenished from a newly generated radical. Thus, the number of extendable chains does not decrease. Figure 9b presents the fraction of dually functionalized chains among initial living chains. The curve for normal ATRP is similar to the one in Figure 9a, as every P-X chain in normal ATRP is terminated with α -R group. Although concentration of extendable chains in ICAR ATRP is constant, due to the replacement of some R-P-X and R-X by I-X and I-P-X, the curve is lower than that in Figure 9a.

The ICAR ATRP curve in Figure 9b is higher than the one for normal ATRP because the termination in ICAR ATRP also involves I-P' species, while the termination in normal ATRP only leads to the decrease in [R-P-X]. Figure 9c illustrates the fraction of extendable chains among all chains present. In a normal ATRP, [all chains] decreases through bimolecular combination and the curve is higher than the corresponding one in Figure 9a. However, in an ICAR system, new chains are gained from the radical initiators and the increase in [all chains] is faster than its decrease caused by combination. Although the number of extendable chains is kept constant, the increase in [all chains] decreases their fraction in final product. The CEF (defined by (14)) shown in Figure 9d is the fraction

of dually functionalized extendable chains among all chains. The decrease in dual-CEF in ICAR system is faster than that in normal ATRP because of newly generated chains.

4 PERSISTENT RADICAL EFFECT

SFRP and ATRP systems are characterized by unusual nonlinear semilogarithmic kinetic plots that obey a peculiar power law. This kinetics was first elegantly explained by Fischer,⁵ who introduced the concept of the PRE in both organic reactions and macromolecular systems. As mentioned before, stable persistent radicals do not terminate, and hence, their concentration progressively increases with the reaction time, shifting the equilibrium in Scheme 3 toward the dormant species. Fischer, and later Fukuda, derived precise kinetic equations to correlate the amount of evolved persistent radical as a function of the overall equilibrium and termination rate constants.^{5,29}

The essence of the PRE can be more clearly explained for systems not complicated by propagation (k_p) and CLDT. Such a simplified system, shown in Scheme 3, consists of three elementary reactions: dissociation (activation) of the alkoxyamine R-Y (k_d), cross-coupling (deactivation) of the transient radical R with persistent radical Y (k_c), and termination of two transient radicals to form product P (k_t).

In this case, the rates of formation of the persistent radical and of loss of the transient radical are given by (15) (the term $2k_t$ is used to be consistent with the earlier published papers):

$$\begin{cases} \frac{dR}{dt} = k_d I - k_c RY - 2k_t R^2 \\ \frac{dY}{dt} = k_d I - k_c RY = \frac{dR}{dt} + 2k_t R^2 \end{cases} \quad (15)$$

The two coupled differential equations were solved analytically by Fischer and independently by Fukuda. They proposed that the increase in concentration of deactivator (Y) should be proportional to $t^{1/3}$ and the loss of transient radical (R) proportional to $t^{-1/3}$ according to the following equation:

$$\begin{cases} Y = (6k_t K_{eq}^2 I_0^2)^{1/3} t^{1/3} \\ R = \left(\frac{K_{eq} I_0}{6k_t} \right)^{1/3} t^{-1/3} \end{cases} \quad (16)$$

Scheme 3

The dependence for the persistent radical Y should be valid in the time interval defined by (17), and (18) should be fulfilled:

$$t_L = \frac{4\sqrt{k_t} K_{eq}}{3I_0^{1/2} k_d^{3/2}} < t < t_U = \frac{I_0}{48K_{eq}^2 k_t} \quad (17)$$

$$K_{eq} < I_0 k_c / 16k_t \quad (18)$$

The dependences described in (15), derived by Fischer and Fukuda, used initial concentration of the initiator (I_0) rather than the actual one, I . However, initiator concentration constantly decreases with the progress of the reaction in all radical systems. It is therefore more accurate to use the actual concentration of the initiator to derive the kinetic equations for transient and persistent radicals, especially when the reactions proceed to higher conversion. A new equation for the evolution of persistent radical during the quasi-equilibrium stage was therefore derived.^{6,30} The derivation is based on the stoichiometric requirement that the amount of persistent radical is equivalent to the number of dead chains, that is, $I_0 - I = Y$, and the assumption that change in the persistent radical concentration is much higher than that for the propagating radicals ($dY/dt \gg -dR/dt$) after quasi-equilibrium is established.

Using variable I , the integration of (3) leads to the following expression:

$$\frac{I_0^2}{I_0 - Y} + 2I_0 \ln \frac{I_0 - Y}{I_0} - (I_0 - Y) = 2k_t K_{eq}^2 t \quad (19)$$

where the persistent radical concentration (Y) is the only variable on the left-hand side of the equation. In a new function $F(Y)$, the only variable is Y:

Figure 10 Evolution of concentrations of all species (solid lines) and concentrations of persistent radical predicted from equation (20) (□) and Fischer's equation (○); $k_d = 0.01 \text{ s}^{-1}$, $k_c = 5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, $k_t = 2.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, $I_0 = 0.05 \text{ M}$. $K_{eq}(\text{calc.}) = 2.0 \times 10^{-8} \text{ M}$. [Reprinted with permission from Ref. 30. Copyright 2006 American Chemical Society.]

Figure 11 Simulated and calculated concentrations of persistent radical derived from equation (20) and Fischer's equation; $k_d = 0.01 \text{ s}^{-1}$, $k_c = 5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, $k_t = 2.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, $I_0 = 0.05 \text{ M}$. $K_{eq}(\text{calc.}) = 2.0 \times 10^{-8} \text{ M}$. [Reprinted with permission from Ref. 30. Copyright 2006 American Chemical Society.]

$$F(Y) = \frac{I_0^2}{I_0 - Y} + 2I_0 \ln \frac{I_0 - Y}{I_0} - (I_0 - Y) \quad (20)$$

A plot of $F(Y)$ versus t provides a straight line with a slope $2k_t K_{eq}^2$. The equilibrium constants for SFRP could be then calculated as $K_{eq} = (\text{slope}/2k_t)^{1/2}$.

The new equations were compared with Fischer's original equations. Calculated values of Y using both equations are plotted versus time together with simulated values in Figure 10. They correspond to alkoxyamine based on St and N-tert-butyl-N-[1-diethylphosphono(2,2-dimethylpropyl)]nitroxide (DEPN) (1-phenylethyl-DEPN) at 120°C .³¹ The data calculated from the new equation match perfectly the simulation once the system reaches quasi-equilibrium, while the plot from Fischer's equation deviates from the simulated values. The apparent deviation ($>30\%$) at long reaction times is illustrated on a linear timescale (Figure 11).

As shown in Figures 10 and 11, Fischer's equation is valid only for a short time period. This period (40–400 s) is much shorter than the time range proposed by Fischer (5.9– 1.0×10^3 s).⁵ The new equation does not have an “upper time limit” and is valid from the moment the system reaches quasi-equilibrium.

This treatment can also be applied to ATRP.⁶ Based on the stoichiometric requirement, that is, $I_0 - I = C_0 - C = Y$ and the assumption

$\frac{dY}{dt} \gg -\frac{dR}{dt}$, new equations were derived for Y as shown in the following equation:

$$\begin{aligned} \text{For } C_0 \neq I_0 \left(\frac{I_0 C_0}{C_0 - I_0} \right)^2 & \left(\frac{1}{C_0^2 (I_0 - Y)} \right. \\ & + \frac{2}{I_0 C_0 (C_0 - I_0)} \ln \left(\frac{I_0 - Y}{C_0 - Y} \right) \\ & \left. + \frac{1}{I_0^2 (C_0 - Y)} \right) = 2k_t K_{ATRP}^2 t + c' \end{aligned}$$

$$\begin{aligned} \text{where } c' &= \left(\frac{I_0 C_0}{C_0 - I_0} \right)^2 \\ & \times \left(\frac{1}{C_0^2 I_0} + \frac{2}{I_0 C_0 (C_0 - I_0)} \ln \frac{I_0}{C_0} + \frac{1}{I_0^2 C_0} \right) \end{aligned} \quad (21)$$

Thus, a new function $F(Y)$ (where Y is the only variable) can be used to calculate K_{ATRP} :

$$\begin{aligned} F(Y) &= \left(\frac{I_0 C_0}{C_0 - I_0} \right)^2 \\ & \times \ln \left(\frac{1}{C_0^2 (I_0 - Y)} + \frac{2}{I_0 C_0 (C_0 - I_0)} \right. \\ & \left. \times \left(\frac{I_0 - Y}{C_0 - Y} \right) + \frac{1}{I_0^2 (C_0 - Y)} \right) \end{aligned} \quad (22)$$

Figure 12 Comparison of the determination of K_{ATRP} using (23) ($F(Y)$ vs t) and the original Fischer's equation ($[Y]$ vs $t^{1/3}$): $[\text{Cu}^{\text{I}}\text{Br}/\text{TPMA}]_0 = [\text{EtBrIB}]_0 = 5 \text{ mM}$, in MeCN at 22°C . [Reprinted with permission from Ref. 6. Copyright 2006 American Chemical Society.]

A plot of $F(Y)$ versus t should be a straight line and the equilibrium constant for the reaction can be calculated from the slope ($K_{\text{ATRP}} = \sqrt{\text{slope}/2k_t}$), with the intercept of c' .

An even simpler equation was derived for the equimolar case:

$$\begin{aligned} \text{For } C_0 = I_0 \\ \frac{C_0^2}{3(C_0 - Y)^3} - \frac{C_0}{(C_0 - Y)^2} + \frac{1}{C_0 - Y} \\ = 2k_t K_{\text{ATRP}}^2 t + c'' \\ \text{where } c'' = \frac{1}{3C_0} \end{aligned} \quad (23)$$

The function $F(Y)$ is now defined as follows:

$$F(Y) = \frac{C_0^2}{3(C_0 - Y)^3} - \frac{C_0}{(C_0 - Y)^2} + \frac{1}{C_0 - Y} \quad (24)$$

A plot $F(Y)$ versus t should be a straight line and the equilibrium constant can be calculated from the slope ($K_{\text{ATRP}} = \sqrt{\text{slope}/2k_t}$), with an intercept of c'' .

The validity of the newly derived equations over a range of conditions was confirmed by experiments carried out for systems with K_{ATRP} ranging from $\sim 10^{-9}$ to as high as $\sim 10^{-6}$ for both nonequimolar and equimolar reactions. When determining the K_{ATRP} , high conversion to X-Cu(II) may be reached. The concentration range of Cu(I) species (C_0) is limited due to its relatively low solubility.

Therefore, an excess of initiator (I_0) over Cu^I species (C_0) was used for reactions with relatively small K_{ATRP} (slow reactions), while equimolar concentrations of I_0 and C_0 were used for reactions with relatively large K_{ATRP} (fast reactions). A typical plot for a reaction with an equimolar concentration of I_0 and C_0 is shown in Figure 12.⁶ The plot is straight with the intercept identical to the expected one ($c_{\text{exp}} = 66.5$, $c_{\text{th}} = 66.5$), giving $K_{\text{ATRP}} = 9.65 \times 10^{-6}$. On the other hand, the plot with $Y \sim t^{1/3}$ shows a pronounced curvature ($K_{\text{ATRP}}(\text{ini}) = 3.58 \times 10^{-6}$, $K_{\text{ATRP}}(\text{final}) = 1.95 \times 10^{-7}$, $K_{\text{ATRP}}(\text{av}) = 4.74 \times 10^{-7}$). The values of K_{ATRP} were obtained for several nonequimolar and equimolar reaction systems using this methodology.

5 SFRP: NITROXIDE-MEDIATED POLYMERIZATION AND ORGANOMETALLIC RADICAL POLYMERIZATION SYSTEMS

SFRP and, more specifically, nitroxide-mediated polymerization (NMP) (see **Nitroxide-Mediated Polymerization and its Applications**)^{7,8} (IUPAC recommends the term *aminoxyl-mediated polymerization*) or organometallic radical polymerization (OMRP)^{9,10} systems rely on the reversible homolytic cleavage of a relatively weak bond in a covalent species to generate a growing radical and a less reactive species (usually the persistent radical, but can also be species with an even number of electrons).^{10,32} This species should react reversibly only with growing radicals and should *not* react among themselves or with monomers to initiate the growth of new chains, and they should *not* participate in side reactions such as the abstraction of β -H atoms.

Nitroxides (aminoxyl radicals) were originally employed as stable free radicals in the polymerization of (meth)acrylates.³³ The field of NMP gained momentum after the seminal paper by Georges *et al.*,⁷ who used 2,2,6,6-Tetramethylpiperidyl-1-Oxyl (TEMPO) as a mediator in St polymerization (Scheme 4). TEMPO and substituted TEMPO derivatives form relatively strong covalent bonds in alkoxyamines that have very low equilibrium constants in NMP (ratio of rate constants of dissociation (activation) and coupling (deactivation), $k_d/k_c = K_{\text{eq}} = 2.0 \times 10^{-11}$

Scheme 4

Scheme 5

M at 120 °C for PS)⁴ and therefore require high polymerization temperatures.

Subsequently, other nitroxides were synthesized that provide a range of C–O bond strengths.^{8,34,35} DEPN³⁶ (also known as *SG-1*) and 2,2,5-tri-methyl-4-phenyl-3-azahexane-3-nitroxide (TIPNO)³⁷ in Scheme 5 contain a H-atom at the α -C. Such nitroxides were originally predicted to be unstable and were expected to quickly decompose. However, the stability of both DEPN and TIPNO is sufficient to control the polymerization of many monomers and a slow decomposition may reduce their accumulation. Polymerization can also be accelerated in NMP systems by a constant radical flux, for example, using slowly decomposing free radical initiators.³⁸ Other systems employing this concept were developed utilizing triazolyl radicals,³⁹ boronyloxy radicals,⁴⁰ and bulky organic radicals such as thermolabile alkanes,⁴¹ (Scheme 5). Alkyl dithiocarbamates, originally used by Otsu *et al.*,^{42,43} undergo homolytic cleavage when irradiated by UV light and can mediate polymerization following an SFRP mechanism. However, the

dithiocarbamyl radicals not only cross-couple but also dimerize and initiate polymerization.

The exploitation of alkoxyamines was originally limited by a lack of efficient synthetic procedures for their preparation, procedures that often resulted in low yields and a wide range of byproducts.^{8,44} However, several versatile techniques have since been developed that involve the controlled generation and trapping of carbon-centered radicals, including single electron transfer reactions associated with ester enolates⁴⁵ and enolate anions.⁴⁶ Another simple method involves halogen abstraction from alkyl halides by a Cu catalyst via atom transfer radical addition and subsequent trapping of the alkyl radical by an excess of nitroxide persistent radical (Scheme 6).⁴⁷

5.1 OMRP Systems

The OMRP of MA with Co porphyrine,⁹ one of the most successful CRP systems, leads to well-defined high MW polyacrylates and has been

Scheme 6

Scheme 7

recently extended to poly(vinyl acetate), though it also includes the DT steps.⁴⁸ However, similar compounds in polymerization of methacrylates act as very efficient catalytic chain transfer agents.⁴⁹ More recently, Co(acac)₂ derivatives were used to control the polymerization of vinyl acetate and *N*-vinylpyrrolidone.^{50,51} Other transition metal complexes (of Mo,⁵² Os,⁵³ Cr,⁵⁴ and Fe^{55,56}) can act as SFRP moderators (Scheme 7). Some of these complexes may also participate in ATRP equilibria (vide infra).¹⁰

5.2 Monomers and Initiators

The range of polymerizable monomers by NMP includes St, various acrylates, acrylamides, dienes,

and acrylonitrile. Monomers forming less stable radicals such as vinyl acetate have not yet been successfully polymerized via NMP because of too low values of K_{eq} , but they were successfully polymerized by OMRP. Disubstituted alkenes such as methacrylates that form more sterically hindered tertiary radicals show difficulties in control by NMP owing to very slow deactivation and/or disproportionation.⁵⁷ Copolymerization with St improves the control.⁵⁸

5.3 General Conditions

The bond dissociation energy (BDE) of most nitroxides and alkoxyamines in NMP is relatively high, and therefore, high temperatures are required. The polymerization of St can be successfully mediated with TIPNO and DEPN at $T > 80^\circ\text{C}$, but with TEMPO, the temperature usually exceeds 120°C . All solvents used in RP can also be employed in NMP. NMP has been successfully used in aqueous systems under homogeneous, emulsion, and miniemulsion conditions.^{59–61} Range of temperatures in OMRP is much larger and temperatures are lower than that in NMP.¹⁰

5.4 Controlled Architectures

NMP has been applied to the synthesis of various homopolymers, statistical, gradient, block, and graft

Scheme 8

copolymers. Star, hyperbranched, and dendritic structures have also been prepared.^{8,35} The range of MWs attainable in NMP is quite large, although transfer can limit MWs at elevated temperatures. Also, nitroxides may abstract β -H atoms and lead to elimination and a loss of functionality in some systems. OMRP was mostly used for synthesis of linear homopolymers, but there are also examples of more complex architectures.

6 ATOM TRANSFER RADICAL POLYMERIZATION

ATRP (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**)^{11,12,62–67} is currently the most widely used CRP technique. This originates from the commercial availability of all necessary ATRP reagents, including transition metal compounds and ligands used as catalysts as well as alkyl halide initiators and also the large range of monomers polymerizable by this technique under a wide range of conditions.

The basic working mechanism of ATRP involves homolytic cleavage of an alkyl halide bond R-X (or macromolecular P_n -X) by a transition metal complex Mt^n/L (such as $CuBr/bpy_2$). This reaction generates reversibly (with the activation rate constant, k_a) the corresponding higher oxidation state metal halide complex $X-Mt^{n+1}/L$ (such as $CuBr_2/bpy_2$) and an alkyl radical $R^\bullet$ (a representative example of this process is illustrated in Scheme 8).^{12,68} $R^\bullet$ can then propagate with a vinyl monomer (k_p), terminate by coupling and/or disproportionation (k_t), or

can be reversibly deactivated by $X-Mt^{n+1}/L$ (k_{da}). Radical termination is diminished as a result of the PRE^{5,6} that ultimately shifts the equilibrium toward the dormant species (activation rate constant $\ll$ deactivation rate constant). The values of the rate constants in Scheme 8 refer to St bulk polymerization at 110 °C.^{69–72}

One important difference between SFRP and ATRP is that kinetics and control in ATRP depends not only on the persistent radical ($X-Mt^{n+1}/L$) but also on the activator (Mt^n/L). MWs are defined by the $\Delta[M]/[RX]_0$ ratio and are not affected by the concentration of the transition metal species. The polymerization rate increases with initiator concentration (P-X) and is proportional to the ratio of concentrations of activator and deactivator:

$$R_p = -d[M]/dt = k_p[M[P^\bullet]] \\ = k_p[M(k_a[P-X][Mt^n/L])/(k_{da}[X-Mt^{n+1}/L])] \quad (25)$$

The synthesis of polymers with low dispersities and predetermined MWs requires a sufficient concentration of deactivator. Dispersities decrease with monomer conversion (p) and concentration of deactivator but increase with the k_p/k_{da} ratio. In the absence of any irreversible chain breaking reactions, dispersities are also lower for higher targeted MW, that is, for lower $[RX]_0$.^{73,74}

$$M_w/M_n = 1 + 1/DP_n \\ + [(k_p[RX]_0)/(k_{da}[X-Mt^{n+1}/L])] \\ \times (2/p - 1) \quad (26)$$

ATRP proceeds via an inner sphere electron transfer (ISET) process, that is, atom transfer. A hypothetical outer sphere electron transfer (OSET, also named as a single electron transfer living radical polymerization)⁷⁵, that is, a two-step pathway through radical anions or dissociative OSET was estimated to be $\sim 10^{10}$ times slower than ISET for model bromoacetonitrile and CuBr/tris[(2-pyridyl)methyl]amine (TPMA) system.⁷⁶ However, under certain conditions, a reduction or oxidation of radicals to carbanions or carbocations by transition metal complexes can occur as a side reaction.^{77,78} Therefore, the appropriate selection of an initiator and catalyst will not only depend on the monomer or targeted molecular architecture but should also be made with respect to plausible side reactions. ATRP with alkyl iodides and dithioesters or trithiocarbonates may also proceed by concurrent DT mechanism, depending on the catalyst and structure of the reagents involved.^{79–84}

6.1 Monomers

The list of monomers successfully homopolymerized by ATRP is quite extensive and includes various substituted styrenes,⁸⁵ (meth)acrylates,^{86–88} (meth)acrylamides,^{89,90} vinyl pyridine,⁹¹ acrylonitrile,⁹² vinyl acetate,⁹³ vinyl chloride,⁹⁴ and others.¹² Nitrogen containing monomers as well as certain dienes can present challenges in ATRP as monomer or polymer complexation to the catalyst can render it less active. Some nitrogen containing monomers can also retard polymerization by displacing the terminal halogen of a growing chain or participating in transfer. Nonpolar monomers such as isobutene^{95,96} and α -olefins^{97–99} were successfully copolymerized using ATRP.

ATRP is tolerant to many functional groups such as hydroxy, amino, amido, ether, ester, epoxy, siloxy, and others. All of them have been incorporated into (meth)acrylate monomers and successfully polymerized. One exception is the carboxylic acid group that can protonate amine-based ligands; it must therefore be protected. However, the polymerizations of methacrylic acid at high pH,¹⁰⁰ styrenesulfonic acid, and acrylamide with sulfonic acid functionality have all been successful in the presence of amines.^{101–104}

Since K_{ATRP} depends very strongly on the structure and reactivity of the monomer and RX, specific

catalysts must be used for different monomers. The order of the equilibrium constants in ATRP, acrylonitrile > methacrylates > St $\sim$ acrylates > acrylamides > vinyl chloride > vinyl acetate, differs from those in SFRP and RAFT due to much larger contribution of polar effects.¹⁰⁵ This order should be followed to efficiently prepare block copolymers, that is, polyacrylonitrile (PAN) should be chain-extended with poly(meth)acrylate and not vice versa. However, it is possible to alter this order using a technique known as *halogen exchange*, whereby a macromolecular alkyl bromide is extended with a less reactive monomer in the presence of a CuCl catalyst.^{106–108} The rationale behind “halogen exchange” is that the value of the ATRP equilibrium constant for alkyl chloride-type (macro)initiators is one order of magnitude lower than the alkyl bromides with the same structure. These C–Cl bonds are activated more slowly, and thus, the rate of propagation is decreased with respect to the rate of initiation. This effectively leads to increased initiation efficiency from the added macroinitiator and preparation of a second block with lower dispersity. In this way, block copolymers were successfully prepared from poly(*n*-butyl acrylate) and extended with PAN or PMMA.^{109,110}

6.2 Transition Metal Complexes as ATRP Catalysts

ATRP has been successfully mediated by a variety of metals, including those from groups 4 (Ti¹¹¹), 6 (Mo^{52,112,113}), 7 (Re¹¹⁴), 8 (Fe,^{93,115–119} Ru,^{62,120} and Os^{53,121}), 9 (Rh¹²² and Co¹²³), 10 (Ni^{124,125} and Pd¹²⁶), and 11 (Cu^{11,12}). Cu is by far the most efficient metal as determined by the successful application of its complexes as catalysts in the ATRP of a broad range of monomers in diverse media. The transition metal complex is very often a metal halide, but pseudohalides, carboxylates, and compounds with noncoordinating triflate and hexafluorophosphate anions were also used successfully.¹²⁷

Ligands include multidentate alkyl amines,^{128,129} pyridines,^{130,131} pyridineimines,¹³² phosphines^{115,133}, ethers, or half-metalocene species.¹³⁴ Ligands serve to adjust the atom transfer equilibrium and to provide appropriate catalyst solubility. Since atom transfer proceeds via a reversible expansion of the metal coordination sphere, the system should be flexible enough to assure a very

fast reversible ISET process.¹³⁵ The atom transfer process should dominate over aforementioned side reactions. Although some catalysts are suitable for several types of monomers, other systems may require a specific catalyst and specific conditions.

The redox properties of the catalyst can be adjusted over a very broad range (>500 mV, corresponding to a range of ATRP equilibrium constants spanning eight orders of magnitude).^{76,136} There is an excellent linear correlation between K_{ATRP} and redox potentials of $\text{Cu}^{\text{II}}\text{Br}_2$ complexes with various N-based ligands.

Another important parameter that affects equilibrium constants is halidophilicity, that is, the affinity of halide anions to the transition metal complexes. For example, since $\text{Cu}(\text{II})$ species typically do not form strong complexes with iodide anion, alkyl iodides are less efficient initiators in Cu-mediated ATRP as could be anticipated from their weak BDE.^{70,76}

6.3 Initiators

The broad availability of initiators is perhaps the most significant advantage of ATRP. In fact, many alkoxyamines and RAFT reagents are prepared from activated alkyl halides, that is, ATRP initiators.^{47,137,138} Essentially, all compounds with halogen atoms activated by α -carbonyl, phenyl, vinyl, or cyano groups are efficient initiators. Compounds with a weak halogen–heteroatom bond, such as sulfonyl halides, are also good ATRP initiators.¹³⁹ There are many compounds with several activated halogen atoms which were used to initiate multidirectional growth to form star-like polymers, brushes, and related copolymers. Activated halogens can be incorporated at the chain ends of polymers prepared by other techniques such as polycondensation, cationic, anionic, ring-opening metathesis, coordination, and even conventional radical processes to form macroinitiators. Chain extensions via ATRP from such macroinitiators were successfully used to form novel diblock, tri-block, and graft copolymers.^{69,140,141} Inorganic surfaces (wafers, colloidal particles, fibers, and various porous structures) were functionalized with ATRP initiators to grow films of controlled thickness and density.^{142–144} Also, several natural products were

functionalized with ATRP initiators to prepare novel bioconjugates.^{145–150}

The reactivity of initiators depends *reciprocally* on the R–X BDE.^{76,151}

6.4 Various ATRP Initiating Systems

ATRP can be conducted over a very broad temperature range: from subzero to >130 °C. Reactions have been successful in bulk, organic solvents, CO_2 , water (homogeneous and heterogeneous—emulsion, inverse emulsion, miniemulsion, microemulsion, suspension, precipitation, and dispersion),¹⁵² and even in the gas phase and from solid surfaces.

For very reactive and reducing catalysts (which are naturally air-sensitive), and for polymerization systems, which are difficult to be deoxygenated (water and large vessels), irreversible oxidation of the catalyst by residual oxygen can lead to failed *normal* ATRP. Thus, alternative systems have been developed. *Reverse* ATRP is a convenient method for avoiding such oxidation problems. In this technique, the ATRP initiator and lower oxidation state transition metal activator ($\text{Cu}(\text{I})$) are generated *in situ* from conventional radical initiators and the higher oxidation state deactivator ($\text{Cu}(\text{II})$).^{153,154} The initial polymerization components are less sensitive to oxygen, and yet the same equilibrium between active and dormant species can ultimately be established as in normal ATRP.

There are several other initiation systems described in detail in chapter on ATRP (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**). Such as *AGET*^{155–160} and processes with very low amounts of copper (ppm) such as activators regenerated by electron transfer (ARGET),^{161–164} and *ICAR*.¹⁶⁵ *ICAR* very closely resembles RAFT. The role of dithioester in RAFT is played by an alkyl halide in the presence of ppm amounts of copper catalysts. The small amount of radical initiator is responsible for continuing polymerization. If the radical source disappears, RAFT stops and *ICAR* would also stop very quickly.

6.5 Controlled Architectures

ATRP has been successfully used to control topology (linear, stars, cyclic, comb, brushes, networks,

dendritic, and hyperbranched), composition (statistical, blocks, stereoblocks, multiblock copolymers, multisegmented block copolymers, graft, periodic, alternating, and gradient copolymers), and functionalities (incorporated into side chains, end groups (homo- and heterotelechelic), and in many arms of stars and hyperbranched materials).^{166–168} In addition, natural products and inorganics were functionalized via ATRP.^{142,149} ARGET and ICAR allow easy access to polymers with designed MW distribution that lead to materials with novel morphologies such as hexagonally perforated lamellae.¹⁶⁹

7 DEGENERATIVE TRANSFER PROCESSES AND RAFT

Conventional free radical initiators are used in DT processes, and control is assured by the presence of transfer agents (RX) that exchange a group/atom X between all growing chains. This thermodynamically neutral (degenerative) transfer reaction should be fast in comparison to propagation ($k_{\text{exch}} > k_p$). At any instant, the concentration of dormant species $P_n\text{-X}$ is much larger than that of the active species P_n^* (~million times). DPs are defined by the ratio of concentrations of consumed monomer to the sum of concentrations of the consumed transfer agent and the decomposed initiator:

$$DP_n = \Delta[M]/([TA] + f \Delta[I]) \quad (27)$$

One exception is when DT reagents are activated by a catalyst, such as copper complexes. In such a case, all chains are generated from transfer agent (TA) since no radical initiator is used.^{81,84}

If transfer is fast and concentration of the decomposed initiator is much smaller than that of the transfer agent, good control can be obtained. Polydispersities decrease with conversion and depend on the ratio of the rate constants of propagation and exchange, according to the following equation⁷⁴:

$$M_w/M_n = 1 + (k_p/k_{\text{exch}})(2/p - 1) \quad (28)$$

DT processes do *not* operate via the PRE. A steady-state concentration of radicals is established via initiation and termination processes.

The simplest example of DT occurs in the presence of alkyl iodides (see **Sb, Bi, Te, and I-Transfer Polymerization and Applications**).¹⁷⁰

Unfortunately, the rate constants of exchange in these systems are typically three times larger than the rate constants of propagation for most monomers, resulting in polymers with dispersities greater than 1.3. They can be accelerated by classical ATRP catalysts or other compounds. As in reversible chain transfer catalyzed polymerization.¹⁷¹ Exchange is faster in other DT processes employing derivatives of Te or Bi (see **Sb, Bi, Te, and I-Transfer Polymerization and Applications**)^{172–175}; consequently, better control was obtained with these systems.

RAFT polymerization is among the most successful DT processes (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).^{137,176–179} While addition–fragmentation chemistry was originally applied to the polymerization of unsaturated methacrylate esters (prepared by catalytic chain transfer (CCT)),¹⁸⁰ RAFT employs various dithioesters, dithiocarbamates, trithiocarbonates, and xanthates as transfer agents leading to polymers with low dispersities and various controlled architectures. The contribution from termination is slightly different in RAFT than it is in SFRP and ATRP. In the latter two systems, all chains are originally short; as they become long, the probability of termination decreases. However, in DT systems, there is always a small proportion of continuously generated new short chains. They terminate faster than long chains. This also makes the formation of pure block copolymers via typical DT techniques impossible, since low MW initiators always generate new homopolymer chains during the polymerization of the second monomer.

7.1 Monomers and Initiators

DT can be applied to any monomer used in RP unless there is some interference with the transfer agent. For example, dithioesters can decompose in the presence of primary amines. RAFT is also suitable to directly polymerize hydrophilic monomers in aqueous media without any protection group chemistry.^{179,181}

In principle, there is no limitation for the radical initiators, but peroxides may oxidize RAFT reagents.¹⁸² Also, initiator concentrations should be

Scheme 9 Order of R group leaving ability in RAFT.

Scheme 10 Rates of addition decrease and fragmentation increase from left to right for RAFT agents with these Z groups.

sufficiently small to assure that large majority of chains originate from the transfer agents and not from radical initiators.

7.2 Transfer Agents

As discussed earlier, transfer agents should be carefully selected for particular monomers in order to provide sufficiently fast addition and also sufficiently fast fragmentation. Alkyl iodides (and derivatives of Te, Sn, Ge, As, or Bi) should have a leaving group R, which provides a more stable radical. Isobutyrate is good for acrylates, but propionate is not efficient in polymerization of methacrylates. This also has implications on the block copolymerization order.

In the RAFT polymerization of MMA with dithiobenzoates ($\text{S}=\text{C}(\text{Ph})\text{SR}$), the effectiveness of the RAFT agent (i.e., the leaving group ability of R) decreases in the order shown in Scheme 9. Only the first two R groups are successful in preparing PMMA with low dispersity ($M_w/M_n \leq 1.2$) and predetermined MW.^{183,184}

Groups Z in RAFT should be more radical stabilizing for monomers forming more stable growing radicals. For the RAFT polymerization of St, the chain transfer constants were found to decrease in the series shown in Scheme 10.¹⁸⁵

7.3 Controlled Architectures

RAFT and other DT systems can be applied to the synthesis of many (co)polymers with controlled architectures. It should be remembered that there

will always be some contamination from chains resulting from the radical initiators, unless a concurrent ATRP/RAFT is employed.⁸¹

Multifunctional RAFT reagents are usually prepared from multifunctional activated alkyl bromides. RAFT reagents can be attached to polymer chains or surfaces via either the R or the Z group. Attachment via the Z group allows polymer chains to grow (and terminate) in solution. This can reduce cross-linking for multifunctional systems.¹⁸⁶

Statistical, block, stereoblock, alternating/periodic, and gradient copolymers were prepared via RAFT. Many functional monomers were polymerized by RAFT. The dithioester group can be removed by the addition of a large excess of AIBN.¹⁸⁷

8 RELATIVE ADVANTAGES AND LIMITATIONS OF SFRP, ATRP, AND DT PROCESSES

Each CRP system has some comparative advantages/disadvantages. Recent advances in all three techniques have minimized many of the disadvantages, but others need to be still eliminated.

8.1 Stable Free Radical Polymerization

The advantages include: (i) purely organic system for NMP, (ii) applicable to acidic monomers, and (iii) no Trommsdorf effect.

The limitations include: (i) relatively expensive moderators must be used in stoichiometric amounts to the chain end, (ii) some limitation for potentially toxic transition metal compounds used in

stoichiometric amounts for OMRP, (iii) difficult to control for polymerization of disubstituted alkenes such as methacrylates, (iv) difficult to introduce CEF, and (v) relatively high temperatures required for NMP.

8.2 Atom Transfer Radical Polymerization

The advantages include: (i) only catalytic amounts of transition metal complexes (commercially available) are necessary; (ii) many commercially available initiators, including multifunctional and hybrid systems; (iii) large range of monomers (except unprotected acids); (iv) easy end-functionalization; (v) no Trommsdorf effect; and (vi) large range of polymerization temperatures.

The limitations are as follows: (i) transition metal catalyst must often be removed and (ii) acidic monomers require protection.

8.3 RAFT and Other DT Processes

The advantages are as follows: (i) large range of monomers and (ii) minimal perturbation to RP systems.

The limitations are as follows: (i) commercial availability of some transfer agents; (ii) dithioester and other end groups should be removed due to color, toxicity, and potential odor; (iii) primary and secondary amine containing monomers as well as basic polymerization conditions lead to the decomposition of dithioesters; and (iv) range of chain end functionalities is limited.

However, recently some of the limitations have been overcome and others may be avoided in future:

NMP: Control of MMA polymerization can be improved in the presence of either new nitroxides or small amounts of St, allowing formation of block copolymers.^{57,58}

ATRP: AGET allows production of clean block copolymers by starting from an oxidatively stable catalyst precursor and employing reducing agents; ARGET and ICAR have lowered the amount of Cu to low ppm amounts and allowed higher MW polymers to be synthesized^{162,165}; new ligands expanded the range of polymerizable monomers to include vinyl acetate and vinyl chloride^{93,94}; simple replacement of a Br end group by azide has

opened many possibilities for functionalization via click chemistry,^{188–190} including new bioconjugates; halogen exchange¹⁰⁶ has allowed the production of some block copolymers with sequences not available via other processes. Kinetically, ICAR resembles RP (such as RAFT).

In RAFT, dithio end groups could be removed in the presence of large excess of AIBN¹⁸⁷; with the rational design of RAFT reagents, retardation and side reactions can be avoided.¹⁹¹ The convergent growth of chains in multifunctional system can prevent macroscopic gelation.¹⁸⁶ Copper catalyst can prevent formation of new chains and allow formation of purer block copolymers.⁸¹

In all systems, a better understanding of the processes in dispersed media has allowed the reduction in the amount of necessary surfactant, has increased colloidal stability, and has also resulted in the extension of miniemulsion to true emulsion, microemulsion, and inverse miniemulsion systems.^{59,61,152,155,167,179,192–195} It has also allowed to form very high MW polymers under high pressure and also with minimal amount of copper.^{75, 196–200}

9 FUTURE PERSPECTIVES

Precise control over molecular architecture via CRP requires the suppression of chain breaking reactions. The development of CRP enabled the synthesis of new materials for specialty applications and helped construction of a much needed correlation between molecular structure and macroscopic properties. There are several reasons why CRP is currently the most rapidly developing area of synthetic polymer chemistry. They include the large range of polymerizable monomers, the simple reaction set-up and undemanding conditions, unprecedented control for an RP, and large potential market for products made by CRP. However, to reach its full potential, more research is needed in various areas of CRP.

Fundamental mechanistic and kinetic studies on all CRP processes are still very necessary. A deeper understanding of structure–reactivity correlation in NMP may lead to satisfactory control over polymerization of methacrylates. The proper choice of dithioesters will decrease retardation effects of some RAFT reagents. A full comprehension of structural effects for ATRP catalysts could lead to the development of even more active complexes that can be used in smaller amounts. This could minimize the

environmental impact of ATRP chemistry as well as expand the range of polymerizable monomers to include (meth)acrylic acid and α -olefins. Some transition metal complexes participate in both ATRP and SFRP and can potentially even be involved in coordination polymerization. This may open an efficient route to the incorporation of polar monomers into a polyolefin backbone.

Model reactions with low MW analogs and oligomers are needed to evaluate penultimate effects and quantify potential chain breaking reactions. Various additives that can accelerate polymerization and provide enhanced microstructural (tacticity and sequence) control should be evaluated. They can increase stereoselectivity as well as chemoselectivity, which are relatively low for radical processes. Better cross-fertilization between synthetic organic chemistry and polymer chemistry is needed. In the past, achievements in organic chemistry were applied to polymer chemistry. However, recent advances made in polymer chemistry have now benefited organic chemistry, for example, new catalysts developed for ATRP are used for atom transfer radical addition and cyclization and new nitroxides developed for NMP are used in organic synthesis.^{201–204}

A deeper insight into the reaction intermediates and energetic pathways will be possible using new techniques offered by computational chemistry. However, precise computational evaluation requires a large basis set, since many reaction pathways may become dramatically affected by tiny changes in the structure of the substituents. Thus, continued model studies and their correlation with macromolecular systems are very much needed to better understand and optimize the existing processes. Computational chemistry has already helped develop new RAFT reagents and may help discover new mediating systems for SFRP and ATRP. Although current CRP techniques seem to cover all major mechanistic approaches to equilibria between active and dormant species, it is feasible to imagine more efficient stable free radicals, more active transition metal complexes, and better DT agents than currently available. Thus, both a serendipitous and rational search (including leads from computational chemistry and model organic systems) for new mediating agents in CRP should continue.

Most CRP reactions are carried out under homogeneous conditions. However, new possibilities

exist when using dispersed systems (microemulsion, inverse emulsion, precipitation polymerization, etc.). Polymerization in confined space may lead not only to new nanocomposites and hybrids but can potentially facilitate additional control over several facets of the polymerization (less termination, stereocontrol, etc.). Cross-linking reactions in CRP provide networks with very different properties than conventional RP.¹⁹⁹ Higher network uniformity leads not only to better swellability but will also be very important for membranes, drug release, and special separation techniques.

CRP has provided access to nearly all macromolecular architectures available from anionic polymerization. However, there are still a few difficult and challenging structures, including heteroarm star polymers, cyclic polymers, and some others. These challenges can be resolved using multifunctional initiators in CRP or special terminating/capping agents. Precise synthesis of polymers with complex architectures must be evaluated by accurate characterization techniques to determine quantitatively the level of functionality, detect existing imperfections, and exactly describe composition, topology, and microstructure. Novel scattering techniques, modulated thermal analysis, detailed mechanical analysis, more sensitive spectroscopic techniques, multidimensional chromatography, and visualization of individual molecules by atomic force microscopy (AFM) are just a few examples of techniques that help characterize the exact structure of prepared materials. There are many remaining challenges in the characterization of gradient copolymers, including measuring the profile and uniformity of the gradient. This is an important issue (from the point of view of intellectual property) since many copolymers prepared by CRP are inherently different from those prepared by RP.

New polymers with precisely controlled architecture are primarily developed to explore novel properties. Such structure–property correlation is very much needed for many applications. Since macromolecular systems are very large and complex, it is difficult to predict all properties by modeling and computational techniques without input from well-defined macromolecules. The detailed correlation of molecular structure with final properties is still not obvious since many properties will also depend on processing conditions, including the solvent used and its removal conditions, mechanical stresses, and thermal history. The incorporation

of such parameters into simulation will be very beneficial.

Additionally, evaluation of all imperfections and synthetic errors on properties of prepared polymers is needed. This should include the effect of polydispersities and shape of MW distribution. Polymers with higher dispersities may form new morphologies with enhanced curvature and bicontinuous sponge-like systems. They can also allow more flexible processing regimes. In CRP, it will be much more economical to prepare polymers faster, with more termination and with more errors. Therefore, it will be important to understand how these imperfections may affect material properties to optimize cost–performance ratio.

In conclusion, CRP has a very bright future, and it is anticipated that many new products will be introduced to the market within the next several years. The annual value of materials made by CRP was recently projected to reach \$20 billion, corresponding to ~10% of all materials prepared by conventional RP. However, reaching this target will require a joint effort from synthetic polymer chemists, polymer physicists, processing engineers, and marketing specialists.

Kinetics of Polymerizations

Michael Buback¹ and Gregory T. Russell²

¹*Institute for Physical Chemistry, University of Göttingen, Göttingen, Germany and* ²*Department of Chemistry, University of Canterbury, Christchurch, New Zealand*

1 INTRODUCTION

1.1 Justification

Worldwide, synthetic polymer production amounts to nearly 200 million tons per annum, approximately half of which is via radical means (see **Radical Polymerization in Industry**).¹ That it is tremendously important to have a detailed understanding of the kinetics of such a process—used to make 100 million tons of product per year!—is a matter so obvious that it should not need any laboring. The close connection between plant safety and control of kinetics adds even further to this importance. Indeed, really the only issue here that is not immediately comprehensible is that so many laboratory chemists have become dismissive of the importance of radical polymerization (RP) kinetics. Mostly, such chemists are in pursuit of new materials. They fail to appreciate or admit two things: (i) The material properties of polymers are intimately connected with quantities such as average molar mass and (copolymer) composition that are determined by polymerization kinetics (Section 2). (ii) The commercialization of any process at the very least involves solid knowledge of its kinetics, and in most cases has the stronger requirement that the kinetics must be favorable. Thus one sees that, far from reaction kinetics being irrelevant to the development of new polymeric materials, it plays an indispensable role.

1.2 Fundamental Reactions

Any description of chemical kinetics must be founded on knowledge of the reactions that occur. Therefore, we begin by illustrating the fundamental reactions of RP. Firstly, there must be a reaction that generates free radicals (see **Overview of Radical Initiation**). Most commonly, this is achieved through thermally induced *decomposition* of a deliberately added chemical *initiator*, for example (di)benzoyl peroxide (BPO):

This process is said to produce *primary radicals*. Ideally, these add to monomer, for example, *tert*-butoxy (e.g., from the initiator di-*tert*-butyl peroxide (DTBP)) with ethylene (IUPAC name: ethene):

A polymer molecule is formed by the continued occurrence of the addition reaction, a process known as *propagation*:

There are three reactions that stop the growth of macroradicals. The most intuitive is *termination* by *combination*, which occurs, for example, in styrene polymerization:⁶

Disproportionation is also a termination reaction in that it results in annihilation of radical activity. It takes place, for example, in polymerization of methyl methacrylate (MMA):⁸

Finally, there are *transfer* reactions, as effected, for example, by a *chain-transfer agent* such as dodecyl mercaptan:

There are quite a few forms of chain transfer to small molecules.^{6,9} Others that are apt to mention here are *chain transfer to monomer*, for example with MMA, and *chain transfer to solvent*, for example with polymerization of vinyl acetate in toluene:¹⁰

All these forms of transfer have in common with termination that they limit polymer growth. However, they are different to termination in that

there is no loss of radical activity *per se*. Ideally the small-molecule radical generated by transfer is like a primary radical in that it adds to monomer and thus initiates the formation of another polymer molecule. This situation is commonly realized; for example, it is the case with the sulfur-centered and monomeric radicals above. However, it is not always the case. For instance, for obvious reasons, the benzyl radical in the example above is relatively stable, and so it retards polymerization by acting as a terminating agent,¹⁰ a process termed *degradative chain transfer*.¹²

1.3 Scope of this Work

It would take a whole book to do full justice to the topic of radical polymerization kinetics. Since this is only an article in an encyclopedia, our focus must therefore be selective. We will not cover here the kinetics of reversible-deactivation radical polymerization (RDRP),^{13,14} as it is covered elsewhere in this encyclopedia (see **Fundamentals of Controlled/Living Radical Polymerization, Nitroxide-Mediated Polymerization and its Applications, Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications, Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**, and **Sb, Bi, Te, and I-Transfer Polymerization and Applications**). Besides, all the reactions considered here occur also in RDRP systems, the kinetics of which must therefore be built upon the foundations presented in this work. Similarly, our slant will not be exclusively based on kinetic equations, for in another book section one of us has recently approached the topic from that angle.⁵ Rather, we will merely summarize the important equations and ideas in Section 2, before taking a mechanistic line of attack in the remainder of this article, so that the reader hopefully emerges with an understanding of the fundamental processes of initiation, propagation, termination, and chain transfer (Section 1.2), all of which should be expected to occur in any radical polymerization. Finally, we will discuss the reactions of chain transfer to polymer and β -scission. These cannot be considered as fundamental RP reactions, because there are many systems in which they do not occur. However, there is growing realization that these

reactions are far more widespread than previously realized, and that, where they do occur, they have a pivotal impact on kinetics and properties.

2 FOUNDATIONS AND MACHINERY

2.1 Reaction Scheme and Population-Balance Equations

A reaction scheme for the fundamental reactions of Section 1.2 is as follows:

Here I denotes initiator, M monomer, R^i (living) radical of degree of polymerization i , D^i dead polymer of degree of polymerization i , X transfer agent, and k a rate coefficient, the subscript to which signifies the reaction involved.

Recognizing that reactions (1)–(5) are elementary in nature, one may immediately write down from this fundamental scheme the following population-balance equations, where c denotes concentration and t time:

$$\begin{aligned} \frac{dc_{R^1}}{dt} = & R_i + k_{trX}c_Xc_{R^1} - k_p c_M c_{R^1} \\ & - k_{trX}c_Xc_{R^1} - 2c_{R^1} \sum_{j=1}^{\infty} k_t^{1j} c_{R^j} \quad (6a) \end{aligned}$$

$$\begin{aligned} \frac{dc_{R^i}}{dt} = & k_p c_M c_{R^{i-1}} - k_p c_M c_{R^i} - k_{trX}c_Xc_{R^i} \\ & - 2c_{R^i} \sum_{j=1}^{\infty} k_t^{ij} c_{R^j}, \quad i = 2, \infty \quad (6b) \end{aligned}$$

$$\begin{aligned} \frac{dc_{D^i}}{dt} = & 2\lambda c_{R^i} \sum_{j=1}^{\infty} k_t^{ij} c_{R^j} + k_{trX}c_Xc_{R^i} \\ & + (1-\lambda) \sum_{j=1}^{i-1} k_t^{j,i-j} c_{R^j} c_{R^{i-j}}, \quad i = 1, \infty \quad (7) \end{aligned}$$

These equations are the source from which all RP kinetics flow. Before making this clear, some essential points about reactions (1)–(5) in relation to (6) and (7) will be made.

For *initiation*, (1), we use R_i for *rate* of creation of polymerizing radicals, rather than a rate coefficient. This is for two reasons: (i) Initiation may occur in a variety of ways⁶—by homolysis of a thermolabile compound, by photolysis of a photoinitiator, by self-reaction of monomer (so-called self-initiation or autoinitiation), and more besides. (ii) There are always side reactions by which primary radicals are squandered before they can initiate polymerization. For both these reasons, initiation does not lend itself to general formalism in terms of a rate coefficient. In the most common case of employing a thermally decomposing initiator—for example, BPO in Section 1.2—one has

$$R_i = 2fk_d c_I \quad (8)$$

where k_d is the rate coefficient for decomposition of initiator of concentration c_I , and f is the so-called *initiator efficiency*, which is the fraction of primary radicals that actually add to monomer and thus successfully initiate polymerization.

Usually, one form of small-molecule *transfer* will be dominant, and one may just use $f_{tr} = k_{trX}c_X$ for the overall *frequency* of transfer, as in (6) and (7). Where it is the case that several transfer reactions occur to a significant extent, one should just use

$$f_{tr} = \sum_{\text{all } X} k_{trX}c_X \quad (9)$$

in all the equations of this work. The other thing to note about transfer is that it is assumed here to involve quantitative reinitiation of polymerization, that is, formation of a R^1 species. Where this is not the case, for example when one has degradative chain transfer, it is not difficult to adapt the equations of this work appropriately.¹⁵

Rather than explicitly including *combination* and *disproportionation*, reactions (3) and (4), respectively, in (6) and (7) we have equivalently used overall rate coefficients for termination k_t^{ij} , and the fraction of termination by disproportionation λ . The simple interrelations here are as follows:

$$k_t^{ij} = k_{td}^{ij} + k_{tc}^{ij} \quad \text{or} \quad k_t = k_{td} + k_{tc} \quad (10)$$

$$\lambda = k_{td}^{ij} / k_t^{ij} = k_{td} / k_t \quad (11)$$

The subscripts “d” and “c” denote disproportionation and combination, respectively.

Chain-length-dependent termination (CLDT) has been included from the outset in (6) and (7). Because termination is diffusion-controlled,^{16,17} immediate intuition is that a termination rate coefficient k_t should depend on the chain lengths i and j of the two radicals involved; hence the notation $k_t^{i,j}$. Over the last decade, it has become possible to confirm this expectation via a variety of experimental methods,^{18,19} with the result that the reality of CLDT is now beyond dispute,¹⁸ and there is little point in pretending otherwise if one is genuinely interested in understanding RP kinetics.

On the other hand, (6) assumes chain-length-independent *propagation*. This is an approximation. Although chemically controlled rather than diffusion-controlled, the body of evidence suggests that for approximately the first 10 propagation steps, values of k_p are elevated above the long-chain value of a system.¹⁵ However, calculations with such a model for CLDP show that it only has a significant effect on overall kinetics if the number-average degree of polymerization DP_n is approximately 100 or less.²⁰ In the usual instance of making long polymer, this will not be the case. Thus it seems reasonable not to account for CLDP here. Where this is necessary, there exist methods for doing so.^{15,20}

In the preceding two paragraphs, note the important distinction between diffusion-controlled and chemically controlled reactions, that is, (bimolecular) reactions for which the rate-determining step is reactant encounter and surmounting a (chemical) energy barrier, respectively. In order to gain understanding of an RP rate coefficient—indeed any rate coefficient—it is first of all essential to be aware of which type of control is operative.

Results that follow from (6) and (7) for quantities of importance are now presented.

2.2 Conversion of Monomer into Polymer

2.2.1 Rate of Polymerization

From reaction (2), the rate of propagation in RP is

$$R_p = k_p c_M \sum_{i=1}^{\infty} c_{Ri} = k_p c_M c_R \quad (12)$$

where the overall radical concentration c_R is as implicit in this equation. The fact that polymer

chains are long means that most of the monomer is consumed by propagation rather than by reactions that start and stop polymer growth: for example, initiation and transfer. Thus to essentially flawless approximation, (12) also gives the overall rate of monomer consumption, that is, the rate of polymerization.

From (6), one may obtain

$$\begin{aligned} \frac{dc_R}{dt} &= \sum_{i=1}^{\infty} \frac{dc_{Ri}}{dt} = R_i - 2 \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} k_t^{i,j} c_{Ri} c_{Rj} \\ &\equiv R_i - 2 \langle k_t \rangle c_R c_R \end{aligned} \quad (13)$$

Implicit in (13) is the following definition of the overall, or chain-length-averaged, termination rate coefficient $\langle k_t \rangle$:^{21,22}

$$\langle k_t \rangle = \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} k_t^{i,j} \frac{c_{Ri}}{c_R} \frac{c_{Rj}}{c_R} \quad (14)$$

Integration of the well-known (13) yields c_R for use in calculating R_p .

For steady-state polymerization (SSP), one has $dc_R/dt \approx 0$, meaning that

$$c_R = \left(\frac{R_i}{2 \langle k_t \rangle} \right)^{0.5} \quad (15)$$

In practice, this equation is accurate as long as there are no abrupt changes in either the rate of initiation or the rate of termination. In other words, it is widely applicable. Substitution into (12) generates the following signature result for RP kinetics:

$$R_p = -\frac{dc_M}{dt} = k_p c_M \left(\frac{R_i}{2 \langle k_t \rangle} \right)^{0.5} \quad (16a)$$

This rate law—and indeed all the familiar results so far—hold also for CLDT, as is implicit.

One might therefore ask why a fuss is made about CLDT. The answer is that it makes $\langle k_t \rangle$ a variable rather than constant quantity. This may be seen from the following steady-state equation for the situation of negligible transfer, where Γ denotes the gamma function:^{23,24}

$$\begin{aligned} \langle k_t \rangle &= k_t^{1,1} \left[\Gamma \left(\frac{2}{2-\alpha} \right) \right]^{-2} \\ &\times \left[\frac{(2R_i k_t^{1,1})^{0.5}}{k_p c_M} \left(\frac{2}{2-\alpha} \right) \right]^{2\alpha/(2-\alpha)} \end{aligned} \quad (17)$$

Strictly speaking, this result holds only for the *geometric-mean* model for termination:

$$k_t^{ij} = k_t^{1,1} (ij)^{-\alpha/2} \quad (18)$$

This is a two-parameter model for CLDT: $k_t^{1,1}$, the rate coefficient for termination between monomeric radicals, stipulates the *magnitude* of k_t^{ij} values, while α , the exponent for variation of $k_t^{i,i}$ with i , quantifies the *strength* of the CLDT, with $\alpha = 0$ returning chain-length-independent termination (CLIT). There are two issues of interest here: (i) Equation (18) is the only model for CLDT that, when introduced into (6) and (7), delivers closed expressions for $\langle k_t \rangle$ and other overall quantities of interest.²⁵ (ii) Numerical solution of (6) and (7) with various CLDT models reveals that they all give results excellently in accord with (17).^{25,26}

Given the above, one may use (17) in (16a) to obtain the following *generally applicable* rate law for steady-state RP in the absence of large amounts of transfer:²⁷

$$R_p \sim (R_i)^{0.5-b} (c_M)^{1+2b} (k_t^{1,1})^{-0.5-b},$$

where $b = \frac{\alpha}{2(2-\alpha)}$ (19)

For the usual situation of $k_t^{1,1} \sim 1/\eta$,^{17,19,28} the order of R_p with respect to viscosity η is $0.5 + b$. Equation (19) correctly recovers the classical rate-law orders of 0.5 for c_I , 1.0 for c_M , and 0.5 for η : these follow from the CLIT value of $b = 0$. The stronger the CLDT, the stronger the deviations from these values. For example, $\alpha = 0.2$ gives $R_p \sim (c_I)^{0.44} (c_M)^{1.11} \eta^{0.56}$, while $\alpha = 0.5$ gives $R_p \sim (c_I)^{0.33} (c_M)^{1.33} \eta^{0.67}$. Equations (17) and (19) may be used to understand trends in $\langle k_t \rangle$ data and to analyze SSP rate data in order to obtain reliable values of α and $k_t^{1,1}$.^{4,29}

2.2.2 Integrated Rate Laws

In terms of the more common index x of fractional conversion of monomer into polymer, (16a) assumes the following equivalent form:

$$\frac{-d \ln(1-x)}{dt} = k_p \left(\frac{R_i}{2\langle k_t \rangle} \right)^{0.5} \quad (16b)$$

This recommends plotting SSP data as $-\ln(1-x)$ versus t , fitting a straight line, and setting the

slope equal to $R_i^{0.5} k_p / (2k_t^{0.5})$.³⁰ An advantage of (16b) is that it is trivially integrated in the event of R_i , k_p , and k_t all being constant with time. The result is

$$x = 1 - \exp(-K't), \text{ where } K' = Kc_I^{0.5}$$

$$\text{and } K = k_p \left(\frac{fk_d}{\langle k_t \rangle} \right)^{0.5} \quad (20)$$

Here, (8) for R_i has been assumed. An example of using (20) to analyze some data^{2,3} is presented in Figure 1.

Equation (20) accounts for change of c_M with time. It is also unavoidable that c_I changes with time. For a thermally decomposing initiator, c_I will decrease from its initial value, $c_{I,0}$, according to the standard first-order rate law $c_I = c_{I,0} \exp(-k_d t)$. Where there is a significant induction time t_{ind} before polymerization commences, then $c_{I,0} \exp(-k_d t_{\text{ind}})$ should be employed as the value of $c_{I,0}$. Using this expression for c_I in (16b) results in

$$x = 1 - \exp \left\{ \frac{-2K(c_{I,0})^{0.5}}{k_d} \left[1 - \exp \left(\frac{-k_d t}{2} \right) \right] \right\} \quad (21)$$

For $k_d t \ll 1$, this reduces to (20).

Figure 1 Fractional conversion x as a function of time t over a limited range only for bulk polymerization of methyl methacrylate initiated by 2,2'-azoisobutyromethyl ester (AIBME) at 50 °C. Points: experimental values;^{2,3} curves: (20) with $K \equiv k_p(fk_d/\langle k_t \rangle)^{0.5} = 1.48 \times 10^{-4} \text{ M}^{-0.5} \text{ s}^{-1}$. This is consistent with the known individual rate coefficients for this system, viz. $fk_d \approx 1 \times 10^{-6} \text{ s}^{-1}$,^{2,3} $k_p \approx 500 \text{ M}^{-1} \text{ s}^{-1}$, and $\langle k_t \rangle \approx 1.25 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$.⁴

Figure 2 Fractional conversion x of monomer into polymer as a function of time t , as evaluated using (21) with $k_p(fk_d/\langle k_t \rangle)^{0.5} = 1 \times 10^{-4} \text{ M}^{-0.5} \text{ s}^{-1}$ and k_d and $c_{I,0}$ as displayed. The parameter values for the unbroken line correspond most closely to those of the data of Figure 1.

Some evaluations of (21) are presented in Figure 2. These make clear the result from (21) that there is a limiting conversion of $1 - \exp[-2K(c_{I,0})^{0.5}/k_d]$. This is the phenomenon of *dead-end polymerization*, where, because either c_I is too low (meaning there simply are not enough initiator molecules for all monomer to be converted into polymer) or k_d is too high (meaning that the formed chains are too short for all monomer to be incorporated), a system falls appreciably short of 100% conversion. These effects are illustrated in Figure 2. At the same time, Figure 2 also makes clear that for “standard” parameter values, for example, those of the data in Figure 1, declining initiator concentration does not prevent all monomer from being consumed. Generally, one only needs to watch out for this phenomenon at high temperatures, where k_d will be large.

2.2.3 Effects of Conversion on Rate Coefficients

Figure 3 shows the data of Figure 1—both experimental and calculated—extended over the entire range of conversion. It is evident that (20) only functions at low conversion as an accurate description of bulk MMA polymerization at 50 °C. This situation is typical, even if often not as pronounced as in

Figure 3 As for Figure 1, except that the *entire range of conversion* is shown. [The Kinetics of Radical Polymerization in Encyclopedia of Polymer Science and Technology, November 2010 in Encyclopedia of Polymer Science and Technology. Copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.]

Figure 3. It arises because of variation of rate coefficients with conversion, giving rise to the two effects highlighted in Figure 3. These are both important, and will now be discussed.

The *gel effect* is an autoacceleration in rate that may occur at intermediate conversion and is also known as the *Trommsdorff effect* or *Trommsdorff–Norrish effect* in recognition of early workers

to report on it.^{31,32} In fact, these are more appropriate names than gel effect: although there is acceleration in rate, as at the gel point of step-growth polymerization, there is no gel formation. Right from the beginning,³³ it was recognized that this effect must be due to changing $\langle k_t \rangle$: as polymer is formed and a system becomes more viscous, the diffusion-controlled nature of termination means that $\langle k_t \rangle$ decreases, and hence rate increases, as is unmistakable in Figure 3. This in turn leads to increase of the molar mass (Section 2.3). For both these reasons, and additionally that of safety (i.e., avoiding runaway conditions), this effect is tremendously important in the modeling of polymerizations. It will be discussed further in Section 5.3, where data will be presented.

One may not so immediately arrive at a qualitative explanation for the *glass effect*, which sees the polymerization all but cease at high conversion (refer to Figure 3). If this were due to macroradical *termination*, then it would require $\langle k_t \rangle$ to increase markedly, which can be ruled out given that the gel effect is due to the opposite. Similarly, although the glass effect looks quite similar to dead-end polymerization (Figure 2), this can be excluded as the cause for several reasons, the most obvious of which is that the appropriate parameter values for the present case result in *initiator* lasting for several days (Figure 2), as opposed to running out after just hours (Figure 3). Since small-molecule diffusion coefficients become very small as a polymer–solvent system becomes glassy, for many years it was believed that the glass effect is due to the *propagation* reaction becoming diffusion-controlled: the idea is that k_p starts to decrease, and this results in a plummeting rate. There is some truth in this explanation, on two fronts: (i) The conversion of the glass effect always corresponds very closely to that at which a system becomes glassy, so the bestowed name is justified. (ii) Measurements show that k_p does indeed start to decrease around the glass transition point.³⁴ However, the same measurements also show that k_p does not decrease by the many orders of magnitude that are necessary to bring polymerization to a halt. Thus, while propagation does contribute, a more complete explanation for the glass effect is that *initiator efficiency* plunges toward zero: the glassy polymer matrix keeps a pair of geminate primary radicals in the vicinity of each other for so long that they can hardly avoid undergoing recombination.³⁵

The above discussion makes clear that $\langle k_t \rangle$ can be expected to change with conversion potentially right from the beginning of a polymerization, while for systems with a glass transition point, k_p will start changing when this point is reached. It is now recognized that f must depend on system viscosity, and thus it too changes throughout the course of a polymerization,^{36,37} with the change being cataclysmic at the onset of glassy conditions.³⁵ Because (20) and (21) assume that all of $\langle k_t \rangle$, f , and k_p are constant in value, they are therefore of limited utility. Rather, the effects of conversion must be taken into account by computer-based modeling that carries out numerical integration of (6) and (7) with rate parameters varying appropriately with conversion. There are countless examples of such undertakings in the literature.

2.3 Molar Masses

As will become clear, this is not a simple topic. Readers not of a mathematical bent may wish to avert their gaze from the equations, and instead focus on the concepts that follow from them. The reason for including the equations is that they are manageable yet still give a highly effective description.

2.3.1 Instantaneous Molar Mass Distributions

Equation (7) defines the *instantaneous number-chain length distribution*, that is, the relative number of (dead) chains of degree of polymerization i being produced at any instant. While this equation may be used as it stands, it is both convenient and instructive to simplify it. For CLIT ($k_t^{ij} = k_t$) and *steady state*, the result is⁵

$$n_i = F_n(1 - S)S^{i-1} + (1 - F_n)(i - 1)(1 - S)^2S^{i-2} \quad (22a)$$

Here n_i is the instantaneous number *fraction* of dead chains of length i (meaning that the sum of all n_i values equals 1), S is the *probability of propagation* (of a radical), and F_n is the *number*

fraction of chains formed by transfer and disproportionation:

$$S = \frac{k_p c_M}{k_p c_M + k_{trX} c_X + 2k_t c_R} \quad (23a)$$

$$F_n = \frac{k_{trX} c_X + 2\lambda k_t c_R}{k_{trX} c_X + 2\lambda k_t c_R + (1 - \lambda)k_t c_R} \quad (24a)$$

For example, if all dead chains are formed by combination, then $F_n = 0$, while if all dead chains are formed by disproportionation and/or transfer, then $F_n = 1$. Note that (22a) may also be derived via probability arguments.³⁸

In the long-chain limit ($S \rightarrow 1$, equivalent to $\nu \rightarrow \infty$), (22a) becomes⁵

$$n_i = F_n \frac{1}{\nu} \exp\left(\frac{-i}{\nu}\right) + (1 - F_n) i \frac{1}{\nu} \frac{1}{\nu} \exp\left(\frac{-i}{\nu}\right) \quad (22b)$$

The new parameter here, ν , is the average number of events that a radical undergoes before it forms a dead chain:

$$\nu = \frac{k_p c_M}{k_{trX} c_X + 2k_t c_R} = \frac{S}{1 - S} \quad (23b)$$

If there is negligible transfer, then ν equals the so-called *kinetic chain length*.¹² The equation numbering here connotes that ν is just an alternative parameter to S . For example, $S = 0.995$ is equivalent to $\nu = 199$.

Equation (22b) is the celebrated *Schulz–Flory distribution* for the chain-length distribution (CLD) from (radical) polymerization (note that in this article the abbreviation “CLD” has a different meaning to that of these letters in “CLDT”). The exponential functions make it more mathematically transparent than (22a), which is actually the *exact* description. One should remember that these equations assume CLIT and SSP. Conversion from CLD into *molar mass distribution* (MMD, vernacularly termed *molecular weight distribution*) is easy: one just uses $M = M_0 i$, where M_0 is monomer molar mass, leading to $dM = M_0 di$ and $d(\log M) = d(\log i)$. This means that $n_M = n_i / M_0$ and $n(\log i) = n(\log M)$. Analogous relations hold for weight distributions. It is slightly more involved to obtain these distributions. The general relationships are,³⁹ illustrated

in each case for the Schulz–Flory distribution:

$$\frac{in_i}{DP_n} \stackrel{\text{def.}}{=} w_i = F_w \frac{1}{\nu} \frac{i}{\nu} \exp\left(\frac{-i}{\nu}\right) + 0.5(1 - F_w) \frac{1}{\nu} \left(\frac{i}{\nu}\right)^2 \exp\left(\frac{-i}{\nu}\right) \quad (25)$$

$$i w_i \stackrel{\text{def.}}{=} \frac{w(\log_{10} i)}{\ln 10} = F_w \left(\frac{i}{\nu}\right)^2 \exp\left(\frac{-i}{\nu}\right) + 0.5(1 - F_w) \left(\frac{i}{\nu}\right)^3 \exp\left(\frac{-i}{\nu}\right) \quad (26)$$

Here, w is weight fraction (i.e., all distributions are *normalized*), and

$$F_w = \frac{k_{trX} c_X + 2\lambda k_t c_R}{k_{trX} c_X + 2\lambda k_t c_R + 2(1 - \lambda)k_t c_R} = \frac{F_n}{2 - F_n} \quad (24b)$$

is the *weight* fraction of chains formed by transfer and disproportionation (cf. F_n). Notice that $F_w = \lambda$ in the event of negligible transfer (11). Equation (26) gives the size-exclusion chromatography (SEC) MMD, so named because it is the form of MMD delivered by this most common experimental technique. It is therefore this equation that should be used to fit experimental data, as now demonstrated.

The equations above show that from five rate coefficients ($f k_d$, k_p , k_{tc} , k_{td} , and k_{trX}) and three reactant concentrations (c_M , c_I , and c_X), MMD actually depends on only two parameters. Considering first F_w (equivalently, F_n), Figure 4 shows that it determines the *shape* (width and height) of an SEC CLD. Thus the first step in fitting (26) to SEC CLD data is to obtain the optimum value of F_w . Having done this, one varies ν (equivalently, S) until the *position* of the fit is optimized: as illustrated in Figure 5, such variation affects only the location of the SEC CLD. In this way, unique F_w and ν values are yielded. What one can extract from these depends on what else is known. If all else is known, then from ν one can obtain the value of k_t and from F_w the value of λ . For example, for bulk styrene polymerization with a high rate of initiation, one would expect transfer to be insignificant. Thus from the value $F_w = 0.25$ fitted to the styrene data,⁷ one deduces $\lambda = 0.25$, that is, 25% of termination is by disproportionation (24b).

Figure 4 Chain-length distributions presented as $w(\log_{10} i)$, where w is weight fraction and i is chain length. Points: results from a low-conversion suspension polymerization of styrene at 80°C .⁷ Curves: Schulz-Flory distributions calculated using (26) with $\nu = 245$ and different F_w as indicated. This illustrates that F_w determines the MMD shape (see text).

Figure 5 As for Figure 4, except that now $F_w = 0.25$ is held constant and ν is varied, thereby illustrating that the latter parameter determines the MMD position (see text).

There is no denying that (22b) provides a flawless fit to the styrene data that has been used for illustration. However, the value $\lambda = 0.25$ is non-physical in that styrene radicals, being secondary in nature, are known to terminate almost exclusively by combination.⁶ This problem may be solved by allowing termination to be chain-length-dependent. For the geometric-mean model, (18), it has been shown that,

in the absence of transfer, the Schulz-Flory distribution becomes⁴⁰

$$n_i = F_n C i^{-0.5\alpha} \exp(-C' i^p) + (1 - F_n) A^2 p i^{1-\alpha} \exp(-A i^p) \quad (27)$$

Here $C = (2R_i k_t^{1,1})^{0.5} / (k_p c_M) = 1/\nu$ (where ν is now for CLDT, cf. (23b) for CLIT), $p = 1 - (\alpha/2)$,

Figure 6 As for Figure 4, except that now the curves are calculated from (27)—that is, allowing chain-length-dependent termination—using $F_w = 0$ (100% combination) together with $\alpha = 0.19$ ($\nu = 135$) and $\alpha = 0.5$ ($\nu = 65$) as indicated. These different ν values were chosen so that $DP_n = 425$ in both cases. [The Kinetics of Radical Polymerization in Encyclopedia of Polymer Science and Technology, November 2010 in Encyclopedia of Polymer Science and Technology. Copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.]

$C' = C/p$, $A = 4C'/(4 - \alpha)$, and F_n is as already defined.

Equation (27) has three parameters: F_n as before, C equivalent to ν , and the new parameter α . Some evaluations are presented in Figure 6, once again using the styrene data as a template. These illustrate that: (i) CLDT acts to broaden MMDs (a point that will be returned to); and (ii) (27) with $\lambda = 0$ and $\alpha = 0.19$ provides a beautiful description of the experimental data.⁴¹ In contrast to the fitting with (22b), both these values are mechanistically plausible: λ as already explained, while this α is spot on for CLDT of long-chain styrene.¹⁸ One may feel highly encouraged by this success.

2.3.2 Instantaneous Number-Average Degree of Polymerization

Number-average degree of polymerization or DP_n is just the arithmetic mean of the number CLD (see below). For the discrete and continuous forms of the Schulz–Flory distribution, (22a) and (22b) respectively, one obtains

$$DP_n \stackrel{\text{def.}}{=} \sum_{i=1}^{\infty} i n_i = F_n \frac{1}{1 - S} + (1 - F_n) \frac{2}{1 - S} \quad (28a)$$

$$\begin{aligned} DP_n &\stackrel{\text{def.}}{=} \int_0^{\infty} i n_i di = F_n \nu + (1 - F_n) 2\nu \\ &= \nu(2 - F_n) = \nu \left(2 - \frac{2F_w}{1 + F_w} \right) \quad (28b) \end{aligned}$$

One sees in these equations the well-known result that combination ($F_n = 0$) gives double the DP_n of disproportionation ($F_n = 1$). A more widely used form⁹ of (28b) is that originally due to Mayo:⁴²

$$\frac{1}{DP_n} = \frac{k_{tr} c_X}{k_p c_M} + \frac{(1 + \lambda)(0.5 R_i \langle k_t \rangle)^{0.5}}{k_p c_M} \quad (29)$$

This suggests plotting data as $1/DP_n$ versus a varied quantity, for example, c_X or $(c_1)^{0.5}$. Such plots are known as *Mayo plots* and the resulting linear fits are used to obtain rate coefficients from the intercept and/or slope.⁹ An example is presented in Section 6. While (29) is parameter-rife, one should not forget the truth of (28): the value of DP_n actually depends on only two composite parameters. A subtle but important change from (28b) and (29) is that from k_t to $\langle k_t \rangle$: in fact these equations hold also for CLDT,^{5,43} even if the Schulz–Flory distribution is only for CLIT.

A *propos* CLDT, in the event of negligible transfer and the geometric-mean model one has

$$DP_n = \Gamma\left(\frac{2}{2-\alpha}\right) \left[\frac{(2R_i k_t^{1,1})^{0.5}}{k_p c_M} \left(\frac{2}{2-\alpha}\right) \right]^{-2/(2-\alpha)} \times \left(\frac{2}{2-\alpha} \frac{2}{1+\lambda}\right) \quad (30)$$

This may be derived either as the first moment of (27)⁴⁰ or, more simply, by substituting (17) for $\langle k_t \rangle$ into (29).¹⁸

The importance of the equations here is that DP_n is the index of polymer size that is most commonly used in correlations for material properties. So these equations are important not only for modeling of material properties but also in establishing that material properties are intimately connected with kinetics, because it is evident that DP_n is entirely a product of polymerization kinetics.

polydispersity index.⁴⁴ The definition and results for (22a) and (22b), respectively, are

$$D_n \stackrel{\text{def.}}{=} \frac{DP_w}{DP_n} = \frac{1}{2}(1 + F_w)(2 + S - F_w) \quad (31a)$$

$$D_n = \frac{1}{2}(1 + F_w)(3 - F_w) \quad (31b)$$

Here, DP_w denotes weight-average degree of polymerization, while the subscript n is used with dispersity to denote that this particular ratio reflects the variance of the *number* CLD³⁸ (analogous to DP_n denoting the mean of this distribution). In the long-chain limit ($S \rightarrow 1$), (31a) is identical to (31b). The latter equation easily yields the textbook results of $D_n = 1.5$ for combination ($F_w = 0$) and $D_n = 2$ for disproportionation and/or transfer ($F_w = 1$).

For CLDT in the absence of transfer, one obtains from (27) that⁴⁰

$$D_n = \frac{1+\lambda}{2} \left\{ \frac{\Gamma\left(\frac{6-\alpha}{2-\alpha}\right)}{\left[\Gamma\left(\frac{4-\alpha}{2-\alpha}\right)\right]^2} + 1 - \lambda \right\} \quad (32)$$

2.3.3 Instantaneous Dispersity

Dispersity D_n is the IUPAC-recommended name for what is commonly but problematically called

This correctly reduces to (31b) for CLIT ($\alpha = 0$). Some evaluations of (32) are presented in Figure 7. This makes clear that both disproportionation/transfer (i.e., increasing λ) and CLDT (i.e.,

Figure 7 Dispersity D_n as a function of CLDT exponent α for $\lambda = 1$ (100% disproportionation), 0.5, 0.2, and 0 (100% combination) as calculated using (32). [The Kinetics of Radical Polymerization in Encyclopedia of Polymer Science and Technology, November 2010 in Encyclopedia of Polymer Science and Technology. Copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.]

increasing α) act to increase D_n (i.e., broaden a MMD). Unfortunately, one cannot discriminate between these two causes of broadening from MMD data alone, as is implicit in the results of Figures 4 and 6. Rather, one needs prior information—for example, independent measurement of the disproportionation-to-combination ratio⁸—in order to be unambiguous in MMD modeling.

D_n is the almost universally used parameter for characterizing MMD broadness. This section has made clear how its value is rooted in kinetics. Once again, one sees the importance of kinetics.

2.3.4 Cumulative Quantities

All the equations presented so far have been for *instantaneous* molar masses. While these equations remain useful for *understanding* molar-mass results, their strict quantitative applicability is necessarily limited to polymer made over narrow conversion ranges. This is because any conversion of monomer into polymer results in change of c_M , which means that ν at the very least will alter in value (23b). But this is just the tip of the iceberg: c_1 will decrease with time (Section 2.2.2), while k_t and f probably will change with conversion (Section 2.2.3). This means that *cumulative* molar-mass quantities—that is, ones from polymerization over any significant interval of conversion—should be modeled via numerical integration of (6) and (7). This will yield c_{Di} (7), the concentration of dead polymer of chain length i , which is a form of the number-CLD. From this, one can then obtain all MMD quantities of interest as above. The commercial package PREDICI⁴⁵ provides a hassle-free way of achieving all this.

2.3.5 General Remarks on Molar Masses

A major aim in studying RP kinetics is to obtain values of rate coefficients, which potentially can depend on many variables: temperature (T), pressure (p), conversion, chain length, viscosity, and perhaps more. Frequently, this is attempted using information on molar mass. While the primacy of polymer molar mass is indisputable, one has to understand that it is difficult to extract unambiguous mechanistic information from MMD quantities, and

it is a dangerous exercise to attempt this. This is so for four different reasons, all of which reinforce each other.

Firstly, most experimental MMDs are from a broad range of conversions, meaning that they are the sum of numerous different instantaneous MMDs (Section 2.3.4). It seems impossibly ambitious that one might deconvolute a cumulative MMD into instantaneous MMDs from which authentic kinetic information may, with confidence, be extracted. This is problematic even where a succession of MMDs has been recorded with conversion. Yes, in principle one may then obtain *pseudo-instantaneous* MMDs through subtraction of cumulative MMDs. But the problem here is that this operation requires very high precision in the SEC signal, and this usually only exists (in terms of relative error) around an MMD peak.

This leads into the second general problem: n_i at small i is very influential in determining DP_n , but it is specifically at small i that the SEC signal—being proportional to $n_i i^2$ ((25) and (26))—is necessarily weak. Thus SEC can never yield the highly important quantity of DP_n with high precision. A visual illustration of this problem is provided by Figure 6. The two calculated MMDs in this figure have the same DP_n , but to the naked eye they look different. This is because the pronounced sections of the MMD at high i have relatively small influence on DP_n , but the sections at low i , where SEC signals are too small to be easily distinguished, have high influence.

Then there is the third problem, which is that SEC is still hostage to significant systematic errors, most notably from calibration,⁴⁶ band broadening,⁴⁷ and baseline selection. As has recently been summarized,⁴¹ all these factors can lead to the *apparent* MMD from SEC being quite different to the *true* MMD.

Finally, there is the problem explained in Section 2.3.3: even if one has a perfectly accurate instantaneous MMD, there can be ambiguity surrounding the mechanistic cause of its width (is it due to CLDT or to combination versus disproportionation/transfer?) and even its position (is it termination or transfer?).

None of this is to deny that molar-mass modeling is of utmost importance and must be carried out. Nor is it to disparage SEC, which has improved to become a very reliable technique and is in no immediate danger of being overtaken by

mass spectrometry (MS),⁴⁸ its only serious competitor, as the preeminent technique for MMD determination of synthetic polymers. However, it is to urge that for genuine mechanistic investigations—as opposed to just arriving at an empirically successful description of MMDs—one should strive as far as possible to determine rate coefficients in separate kinetic experiments, preferably ones that are rate-based. This is especially so for $\langle k_t \rangle$ determination, in particular in regard to its conversion and chain-length dependences.³⁰ Armed with information from such experiments, one may then attack the task of understanding molar-mass information. For this, we strongly recommend modeling the entire MMD, as opposed to just seeking to reproduce an average molar mass and perhaps the dispersity. Given the discussion above, the reasons for this recommendation should be obvious.

2.4 Copolymerization

The fundamental equations above hold unchanged for copolymerization. What makes things more involved is that rate coefficients become averages over some composition. This issue is most important for propagation, and so for good reason it has received by far the greatest amount of attention. This is not just because k_p is paramount in determining rate and molar mass, but also because, as will shortly be seen, propagation alone determines *composition*, which is a vitally important copolymer quantity.

The *terminal model* (TM) for (binary) copolymerization propagation is

This says that k_p is influenced both by the monomer and the radical-bearing end unit of a growing chain. Even a non-chemist could hardly deny that matters cannot be any simpler than this. It turns out that the TM often does a sterling job of describing copolymerization data, as will be seen. For where it is insufficient, there are a plethora of more elaborate models to choose from. These have been reviewed elsewhere⁴⁹ and will not be described here. This is because most of these models may now be seen as flights of fancy. Ever since Fukuda *et al.*'s epochal paper of 1985,¹¹ the plausibility of

the *penultimate model* (PM) could not rationally be gainsaid. This model allows radical reactivity also to depend on the second monomer unit from the end of a chain:

Again, most chemists would regard this model as a matter of common sense, because part of the richness of chemistry is that the reactivity of functional groups is influenced by what is two or more bonds away from them. It may well be that there are other complicating factors at work in copolymerization, but these are unlikely to be as significant as that of the penultimate unit on k_p . Further, fact is that it is very rare for the PM, with its eight rate coefficients, not to be able to provide a global description of all data. Therefore, there is essentially no need to go beyond the model of (34).

2.4.1 Instantaneous Copolymer Composition

A very important copolymerization quantity is average whole-chain composition, that is, the fraction F_1 of residues of monomer type 1 in the polymer chains. This is because material properties of copolymers are intimately linked to F_1 . One of the most famous results in polymer science is

$$F_1 = \frac{r_1 f_1^2 + f_1 f_2}{r_1 f_1^2 + 2f_1 f_2 + r_2 f_2^2} \quad (35)$$

where f_1 is the mole fraction of monomer 1 in the binary monomer mixture. For the TM, the two (*monomer*) reactivity ratios are $r_a = k_{p,aa}/k_{p,ab}$, where $a, b = 1$ or 2 and $b \neq a$. These capture the relative preference of a particular radical for the two different *monomers*. Equation (35) still holds for the PM, but the r_a 's are more complicated, as follows:⁴⁹

$$r_a = r_{ba} \frac{r_{aa} f_a + f_b}{r_{ba} f_a + f_b}, \text{ where } a, b = 1 \text{ or } 2 \quad \text{and } a \neq b \quad (36)$$

$$r_{aa} = \frac{k_{p,aaa}}{k_{p,aab}} \text{ and } r_{ba} = \frac{k_{p,baa}}{k_{p,bab}}, \quad \text{where } a, b = 1 \text{ or } 2 \text{ and } a \neq b \quad (37)$$

Figure 8 Mole fraction F_{sty} of styrene in copolymer as a function of mole fraction f_{sty} of styrene in monomer feed for styrene/methyl methacrylate bulk, low-conversion copolymerization at 40 °C. Points: experiment;¹¹ lines: evaluations of (35) with (constant) r values as displayed, where the unbroken line is the best (nonlinear least squares) fit to the data.

Thus now composition depends on four reactivity ratios rather than two. In both cases, F_1 depends only on ratios of $k_{p,(c)ba}$ values, not the values individually.

To obtain the r values, (35) should be fitted by nonlinear least-squares to experimental measurements of F_1 as a function of f_1 . An example is presented in Figure 8. It is evident that an exemplary fit is obtained with the TM, with constant values of r_1 and r_2 (cf. (36)). Examples where the PM is necessary for the fitting of composition data are rare but do exist, for example, styrene/acrylonitrile.⁵⁰ In the usual instance, there is no need to invoke (36).

It is instructive to evaluate (35) for some other pairs of r values. Results are also presented in Figure 8. One sees that, in this case, changing each best-fit value of r by a factor of (approximately) 2 does not have a profound effect, while changing them both by this amount actually keeps the composition curve in the vicinity of the data throughout (although admittedly $r_1 = r_2 = 1$ does make the system azeotropic under all conditions, a significant change). It is stressed that these effects vary with the r values. Nevertheless, these calculations give some insight into the difficulty of obtaining r values with high precision.

It is important to be clear that (35) is for *instantaneous* copolymer composition, that is, the copolymer produced at any instant. Thus it should

only be used for data gathered over a small range of conversion. Where there is significant change in conversion, there will be change of f_1 due to monomer consumption being at a different ratio (except in the rare event of $F_1 = f_1$, i.e., *azeotropic* conditions). This means that F_1 will change from instant to instant: so-called *composition drift* occurs. In this event, one should use an integrated composition equation to fit cumulative (average) F_1 data.

2.4.2 Overall Propagation Rate Coefficient

The following equation gives the value of k_p for SSP of two monomers:⁴⁹

$$k_p = \frac{r_1 f_1^2 + 2f_1 f_2 + r_2 f_2^2}{\frac{r_1 f_1}{k_{p,11}} + \frac{r_2 f_2}{k_{p,22}}} \quad (38)$$

A common misconception is that this equation with fixed r cannot adequately fit copolymerization k_p data. In fact, such data can be very well fitted in this way,⁵¹ but the problem is that the r values so obtained are quite different to those from fitting of composition data. As will be seen (Section 4.3.1), there is plentiful evidence that r

Figure 9 Overall propagation rate coefficient k_p as a function of mole fraction f_{sty} of styrene in monomer feed, for styrene/methyl methacrylate bulk, low-conversion copolymerization at 40 °C. Points: experiment;¹¹ lines: implicit-penultimate-model calculations ((38) and (39)) with s values as displayed and with $r_{\text{sty}} = 0.523$ and $r_{\text{MMA}} = 0.461$ (Figure 8). The unbroken line is the best (nonlinear least squares) fit to the data, while the dotted line ($s_{\text{sty}} = s_{\text{MMA}} = 1$) is the terminal-model prediction for this dataset.

values from composition correspond to the physical truth. When one uses such values in (38), usually an unacceptably inaccurate prediction for $k_p(f_1)$ is obtained, as is illustrated in Figure 9 for the system of Figure 8.

This highly unsatisfactory situation was first fully exposed by Fukuda *et al.*¹¹ and their explanation has stood the test of time: the PM is at work in copolymerization k_p . With this model, (38) still holds, but values in it vary with f_1 , the r_a according to (36), and the $k_{p,aa}$ according to:⁴⁹

$$k_{p,aa} = k_{p,aaa} \frac{r_{aa}f_a + f_b}{r_{aa}f_a + \frac{f_b}{s_a}}, \text{ where } a, b = 1 \text{ or } 2$$

$$\text{and } a \neq b \quad (39)$$

$$s_a = \frac{k_{p,baa}}{k_{p,aaa}}, \text{ where } a, b = 1 \text{ or } 2 \text{ and } a \neq b \quad (40)$$

The s_a 's are called *radical reactivity ratios*, because, whereas it is the monomer that varies in the r ratios, it is the penultimate radical unit that varies in the s ratios. This immediately implies that one should expect different behaviors from these two types of ratio.

The above development immediately raises two important issues. First, how should one deal with

the proliferation of parameters from four (TM) to eight (PM) involved in k_p prediction, an increase that provides too much flexibility in data fitting? Secondly, how to explain that, if the PM is necessary to understand k_p , then why is it not needed for F_1 data? Happily, Fukuda *et al.*¹¹ were immediately able to find a satisfactory explanation that eliminates both these problems. To wit, they reasoned that the absence of any regular need for the PM to describe composition data may be interpreted as likely evidence that $r_{21} \approx r_{11}$ and $r_{12} \approx r_{22}$, in which event the TM for composition is recovered (36). At first sight, this seems to contradict the very premise of the PM, but not when one thinks about it more closely: it seems quite reasonable to have that the penultimate unit affects the absolute value of $k_{p,cba}$ but not so much the *ratio* involved in r_a ; indeed, transition state (TS) theory provides support for this notion.⁵² This being the case, one has the far more manageable situation of introducing only two extra parameters, s_1 and s_2 , for describing k_p data.

By now, the idea that $r_{21} = r_{11}$ and $r_{12} = r_{22}$ has come to be known as the *implicit penultimate model* (IPM),⁵³ meaning that there is a penultimate-unit effect in propagation but it is not explicitly observable in composition, only in (overall) k_p . Most copolymerization datasets (F_1 and k_p) can be flawlessly described by this model, as is illustrated for

styrene/MMA in Figure 9. The procedure is that one fits F_1 with the TM ((35); e.g., Figure 8), and then one uses the so-obtained r values in fitting k_p data with the PM ((38) and (39)) such that only s_1 and/or s_2 may be varied (e.g., Figure 9). Only in rare cases is this procedure—the IPM—not adequate (see Section 4.3.2 for an example).

One must be aware that, just because the IPM works, this does not guarantee that the obtained reactivity ratios values represent the physical truth. A number of workers have explored this theme.^{51,54,55} Particularly worthy of mention is that (i) composition data is only weakly sensitive to deviations of r_{21} from r_{11} and r_{12} from r_{22} , meaning that success with $r_{21} = r_{11}$ and $r_{12} = r_{22}$ does not mean these equalities strictly hold;⁵⁴ (ii) k_p data usually is not sensitive to *both* s_1 and s_2 , but only to one of them.⁵⁵ This is illustrated in Figure 9, where it is shown that variation of s_{MMA} has only a very weak effect on calculated values of k_p . This means that this data does not deliver the value of s_{MMA} with even crude precision.^{5,55}

2.5 Pulsed-Laser Polymerization

The idyll of pulsed-laser polymerization (PLP) is sufficiently closely realized that it can be considered a reality. It is that a laser pulse instantaneously creates a crop of uniformly sized small radicals from photoinitiator, and thereafter there is no new radical generation (until the next pulse). Thus PLP is essentially the antithesis of SSP, because the system is permanently in a nonsteady (or nonstationary) state. There are several other long-known techniques for effecting nonsteady-state polymerization (NSSP),³⁰ but all have been rendered virtually redundant by the advent of PLP in the mid-1980s. This is because PLP may be employed in two particularly potent ways, as now described.

2.5.1 Single-Pulse PLP for Measuring Termination Rate Coefficients

PLP creates a monodisperse crop of radicals of size $i = 1$ at time $t = 0$. These then grow with time. Although there is some broadening of the distribution of sizes due to the stochastic nature

of propagation (leading to a Poisson distribution), to excellent approximation one can regard the population as remaining of single size given by $i = k_p c_M t + 1$.⁵⁶ This assumes that initiation *and* transfer—both leading to generation of small radicals—occur to a negligible extent during this period. For the most part, these are reasonable assumptions. What it leads to is that the termination rate at any instant is that between radicals of identical chain length, and so by measuring this rate one can obtain $k_t^{i,i}$. Further, as time goes on, a complete range of i will be traversed, meaning that in principle one can obtain the entire variation of $k_t^{i,i}$ with i .

This is the so-called single-pulse PLP (SP PLP) method for measuring termination rate coefficients. While this exceptional potential for determining CLDT rate coefficients was grasped some decades ago,⁵⁷ its widespread realization¹⁹ has occurred only in recent times with the coupling of the technique to electron paramagnetic resonance (EPR) spectroscopy (see **Analysis of Radicals by EPR**).⁵⁸ c_R is *directly* measured on a microsecond timescale by quantitative EPR, and the resulting variation is analyzed to obtain $k_t^{i,i}$. Ideally, one could differentiate the experimental data and thence obtain model-free $k_t^{i,i}$ from dc_R/dt ; however, in practice it has been found better to assume a power-law model for $k_t^{i,i}$ (e.g., (18)):

$$k_t^{i,i} = k_t^{1,1} i^{-\alpha} \quad (41)$$

When this is introduced into (13), one obtains for SP PLP⁵⁶

$$\frac{c_{R,0}}{c_R} - 1 = \frac{2c_{R,0}k_t^{1,1}}{k_p c_M (1 - \alpha)} [(k_p c_M t + 1)^{1-\alpha} - 1] \quad (42)$$

where $c_{R,0}$ is the radical concentration created by the laser pulse, which of course is measured as part of the experiment. An example of fitting SP PLP EPR data with (42) to obtain α and $k_t^{1,1}$ is given in Figure 10.⁵⁹ This illustrates the unique potency of the method for investigating CLDT of relatively small radicals, i.e., determining $k_t^{1,1}$ and α for small chains.

There are two important limits of (42). The first is that, for long times⁵⁸

$$\frac{c_{R,0}}{c_R} - 1 = \frac{2c_{R,0}k_t^{1,1}(k_p c_M)^{-\alpha}}{(1 - \alpha)} t^{1-\alpha} \quad (43)$$

Figure 10 Radical concentration, plotted as $c_{R,0}/c_R - 1$, versus time t for a typical SP PLP EPR experiment. Points: data for 1.5 M methyl acrylate in toluene at -40°C ; line: (42) with best-fit values of $\alpha = 0.82$ and $k_t^{1,1} = 1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.⁵⁹

This suggests plotting data as $\log(c_{R,0}/c_R - 1)$ versus $\log t$, fitting a straight line, and very simply extracting α from the slope.⁵⁸ This approach has been used for studying long-chain termination via SP PLP EPR.¹⁹

The second limit is that of CLIT, that is, $\alpha = 0$:

$$c_R = \frac{c_{R,0}}{2k_t c_{R,0} t + 1} \quad (44)$$

With this expression, (12) is integrable, giving the result

$$\frac{c_M}{c_{M,0}} = (2k_t c_{R,0} t + 1)^{-k_p/(2k_t)} \quad (45)$$

Here, $c_{M,0}$ is the monomer concentration at the time of laser pulsing. Equations (44) and (45) are the basis of the long-standing⁶⁰ SP PLP NIR method for k_t determination: near-infrared (NIR) spectroscopy is used to monitor c_M on a microsecond timescale, and the resulting variation is fitted with (45) to obtain k_p/k_t , from which k_t can be procured if k_p is known. It is a universal feature of NSSP methods that they yield k_p/k_t , whereas SSP methods all yield $k_p/(\langle k_t \rangle)^{0.5}$, for example see (16) and (29).³⁰ As the notation here implies, the k_t yielded by NSSP experiments is more complicated in that it is an average over both time and chain length.

The conversion consequent upon a single laser pulse is usually extremely small, much less than 1%.

Thus SP PLP—whether carried out in conjunction with EPR or NIR—may be used to map out the variation of termination rate parameters with conversion in extremely fine detail, far more so than with any other method:³⁰ one simply has to start an SP PLP experiment and continue to make measurements as conversion slowly increases under the action of the laser. This is another reason why SP PLP has been recommended as the premier method for studying termination kinetics in RP.³⁰

2.5.2 Multiple-Pulse PLP for Measuring Propagation Rate Coefficients

Consider carrying out a PLP in which laser pulses periodically strike at intervals of t_d (standing for “dark time”). This situation will be termed *multiple-pulse PLP* (MP PLP). When a new pulse arrives, the radical CLD will consist of essentially monodisperse populations of sizes $k_p c_M t_d$, $2k_p c_M t_d$, $3k_p c_M t_d$, and so on, from previous pulses: this follows from the principles explained above. As a result of the new pulse, these populations will be suddenly subjected to a vastly increased frequency of termination, because of the creation of a whole host of new radicals. Thus there will be a marked increase in the production of dead chains around sizes $k_p c_M t_d$, $2k_p c_M t_d$, $3k_p c_M t_d$, and so on.

Figure 11 Results from simulation of a multiple-pulse PLP with $k_{pCM} = 2000 \text{ s}^{-1}$, $k_t = 1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, $c_{R,0} = 5 \times 10^{-8} \text{ M}$, $t_d = 0.1 \text{ s}$, $\lambda = 1$, and $k_{trX} = 0$.⁶² Full line: $w(\log_{10} i)$, where w is weight fraction and i is chain length; broken line: $dw(\log_{10} i)/d \log_{10} i$; dotted vertical lines: positions of chain lengths (left to right) $k_p c_M t_d$, $2k_p c_M t_d$, and $3k_p c_M t_d$, showing that these are very close or equal to positions of the maxima in the derivative trace.

Therefore if the dead-chain CLD is determined at the end of the experiment, it will contain identifiable features at these chain lengths, designated i_n . By reading off these values, it is a simple matter to determine k_p , because t_d (the inverse of the laser pulsing frequency) and c_M are easily controlled and known:

$$k_p = \frac{i_n}{n t_d c_M}, \quad n = 1, 2, 3, \dots \quad (46)$$

This was the revolutionary idea published by Olaj *et al.* in 1987.⁶¹

A theoretical validation of this idea is presented in Figure 11, which shows a set of results⁶² from numerical solution of (6) and (7) for the situation of MP PLP. It is evident that the chain length $k_p c_M t_d$ and its integer multiples lie a little to the low-molar-mass side of the CLD peaks rather than exactly at their center. The reason for this was realized right from the beginning:⁶¹ the radical CLD consists of Poisson distributions and termination is not instantaneous. Without either one of these conditions, $k_p c_M t_d$ corresponds to the peak positions. How then to determine k_p ? Workers have remained with Olaj *et al.*'s initial suggestion of using the position of the point of inflection on

the low-molar-mass side of each CLD peak.⁶¹ It is shown in Figure 11 that these features give $k_p c_M t_d$, and hence k_p , accurately. However, one should always remember that this is not an *exact* result, and so it introduces a small but unavoidable degree of systematic error into the values of k_p obtained by this technique. Again, this is evident in Figure 11.

That is the theory: what about reality? A typical set of results is presented in Figure 12.⁶³ It is clear that in essence the theoretical expectations of Figure 11 are observed. The major difference is that SEC column broadening acts to disperse the sharp features of the theoretical CLD. Nevertheless, these features are still clearly visible in the actual CLD, and it has been confirmed that this broadening does not undermine k_p determination.⁶⁴ This study also illustrates how the sharpness and relative intensities of the PLP-induced peaks are a function of the parameters k_t , $c_{R,0}$, and t_d , but that this also does not affect k_p determination.⁶⁴ Standard practice is to use only the first MMD inflection point ($n = 1$ in (46)) for quantitative k_p determination, because the first maximum in experimental derivative traces is far more strongly evident than the higher order maxima, as may be seen in Figure 12. Instead, these are best employed as “consistency

Figure 12 Results from an MP PLP of bulk methyl methacrylate at 40 °C with $t_d = 0.1$ s.⁶³ Full line: $w(\log_{10} i)$, where w is weight fraction and i is chain length; broken line: $dw(\log_{10} i)/d \log_{10} i$; short dotted vertical lines: positions of chain lengths (left to right) 460, 2×460 , and 3×460 , making it clear that the positions of the maxima in the derivative trace are (close to) equal to multiples of $k_p c_M t_d$. This material is reproduced with permission of John Wiley & Sons, Inc.]

checks”: their position should be close to the appropriate multiple—see (46)—of the position of the first peak for the obtained value of k_p to be considered robust.⁶⁵ Again, Figure 12 exemplifies the successful meeting of this criterion.

It took only a short time before the MP PLP method was recommended by IUPAC as the method of choice for k_p determination.⁶⁵ Reviews testify to how widely and successfully it has been deployed.^{66,67} The major reasons for this are the intuitive nature of the method and the fact that it is independent of knowledge of essentially all other rate parameters.

3 INITIATION

An excellent survey of the experimental methods and kinetic results about initiator decomposition is given in Moad and Solomon's book.⁶ A variety of methods have been used for detection of the disappearance of initiators and the appearance of products from initiator decomposition. They encompass spectroscopic methods such as UV–vis and IR–NIR spectroscopy. Trapping techniques have been employed and the type and concentration of the so-obtained primary adducts have been

measured. Most recently, electrospray ionization (ESI) mass spectroscopy on oligomeric species has turned out to be a promising method for detection of the type of initiator fragments that start macromolecular growth by addition to a monomer molecule.^{68–71}

The two pieces of kinetic information that are essential knowledge in applying chemical initiators in RP are (Section 2.1) decomposition rate coefficient k_d , which defines decline in initiator concentration with time, and efficiency of initiation f , which indicates the fraction of primary radicals that start chain growth. As initiator decomposition rates are mostly determined in independent experiments by monitoring initiator decay in an inert solvent, it is recommended to employ a solvent as similar as possible to the monomer system of interest, since k_d depends on solvent properties. Of course, f can be measured only in the presence of monomer (without which $f = 0$ by definition). In any event, the solvent in which k_d has been measured should be stated when presenting polymerization data. As an example, for use with ethylene polymerization, k_d values from decomposition experiments of initiators dissolved in compressed *n*-heptane appear to be appropriate.

There are a number of classes of chemical initiators, for example, azo compounds, dialkyl peroxides, hydroperoxides, peroxyesters, diacylperoxides, peroxycarbonates, and peroxydicarbonates (see **Overview of Radical Initiation**). In what follows, we present aspects of using peroxyesters, $R(CO)OOC(CH_3)_2R^*$, as a source of primary reactive species for RP. Of course, the general principles thus revealed should hold also for other classes of initiators, and the presented values of rate parameters give a feel for these with all initiators.

3.1 Decomposition Rate Coefficients

Quantitative IR spectroscopy has turned out to be very useful for measuring the decay of peroxide concentration or, alternatively, the increase in the concentration of products from decomposition. Two discontinuous procedures have been used:

1. At lower reaction temperatures, the peroxide solution is contained in an internal cell, which is filled and assembled in a glove box under an argon atmosphere. The internal cell is positioned into an optical high-pressure cell and pressurized with *n*-heptane acting as the pressure-transmitting medium. The assembly is heated to the reaction temperature and the collection of IR spectra is started. In the case that the decomposition rate becomes too fast and a major fraction of the peroxide is decomposed before reaction conditions of constant T and p are reached, the peroxide solution is directly fed into a pre-heated autoclave. The solution is then quickly pressurized and the collection of IR spectra is started.
2. Kinetic analysis under conditions where decomposition is fast, for example reaction half-lives well below 1 minute, has been performed using a tubular reactor which essentially consists of a high-pressure capillary of 10 m (or even longer) length and 0.5 mm internal diameter.⁷² The IR spectroscopic analysis is performed at reaction pressure, but at lower temperature, in an optical cell that is positioned directly behind the tubular reactor.

A wide variety of peroxyesters with the general structure $R(CO)OOC(CH_3)_2R^*$ —see Figure 13—are commercially available,⁷³ where R and R^* may

Figure 13 General structure of a peroxyester, with the arrows indicating the positions where bonds may break during initiator decomposition.

be primary, secondary, or tertiary alkyl groups such as methyl, ethyl, *iso*-propyl, and *tert*-butyl. The primary step of thermally induced initiator decomposition consists of breaking the O–O bond. In the case of very fast or even concerted successive bond scission of the primary radical fragments from initiator decomposition, the overall decomposition rate coefficient k_d may be affected. The follow-up reactions chiefly are β -scission reactions, in which the labile bond in a β -position to the radical functionality is broken. An important such β -scission process is decarboxylation of the primary radical $R(CO)O\cdot$. Also, the second radical fragment from peroxyester decomposition, $OC(CH_3)_2R^*\cdot$, may undergo β -scission, forming acetone plus an R^* radical. The β -scission reactions are particularly fast in cases where a stable radical, for example, a *tert*-butyl radical, is produced.

The k_d values of primary peroxyesters—i.e., where R is CH_3 or CH_2R' —are more or less identical at the same temperature and pressure, whereas the type of R moiety matters with secondary and tertiary peroxyesters. This difference between primary peroxyesters on the one hand and secondary and tertiary peroxyesters on the other is understood as being due to close-to-concerted β -scission with secondary and tertiary peroxyesters but slow β -scission with primary peroxyesters. Within the latter group of initiators, the R group of the $R(CO)O$ moiety is too far away from the peroxy linkage to affect the primary decomposition of the O–O linkage of the peroxyester. The opposite is the case with tertiary peroxyesters, where the stable tertiary radical is immediately formed and the specific type of R moiety thus affects decomposition kinetics.

This interpretation is supported by the activation energies measured for the overall first-order decomposition rate coefficients k_{obs} of peroxyesters.^{74,75} In Figure 14, numbers for the activation energy at low pressure $E_A(0 \text{ bar})$ are plotted against the bond

Figure 14 Activation energy $E_A(0 \text{ bar})$ of the decomposition rate coefficient for *tert*-amyl (filled circles; $R^* = \text{ethyl}$) and *tert*-butyl (open circles; $R^* = \text{methyl}$) peroxyesters at low pressure as a function of bond dissociation energy of the associated alkane $BDE(R-H)$. PP: peroxypivalate; PO: peroxy-2-ethylhexanoate; PiB: peroxy-*iso*-butyrate; PnB: peroxy-*n*-butyrate; PA: peroxyacetate. [Reproduced with permission from Ref. 75. © Oldenbourg Verlag, 2003.]

dissociation energy of the R–H bond $BDE(R-H)$, which serves as a measure of the stability of the radical R. For primary peroxyesters, the activation energy is insensitive toward $BDE(R-H)$, whereas for secondary and tertiary peroxyesters the stability of R clearly matters. Further, $E_A(0 \text{ bar})$ of secondary and tertiary peroxyesters is linearly correlated with the associated $BDE(R-H)$, indeed, the correlation has unity slope. As shown, these trends are the same for both *tert*-butyl and *tert*-amyl peroxyesters, that is, they are independent of R^* . This indicates that the correlation essentially reflects the decarboxylation process of the $R(\text{CO})\text{O}$ radical.

Similarly, the pressure dependence of k_{obs} is clearly different for primary peroxyesters on the one hand and for secondary and tertiary peroxyesters on the other.^{74,75} Plotted in Figure 15 are values of $k_{\text{obs}}/k_{\text{obs}}(2000 \text{ bar})$, that is, decomposition rate coefficient relative to the value at 2000 bar. Secondary and tertiary peroxyesters behave similarly in that they exhibit a weak decrease of k_{obs} toward higher pressure, whereas primary peroxyesters show a pronounced decrease. This difference is explained as follows: In the case of primary peroxyesters, the

activation volume is assigned to single-bond scission, which is associated with a pronounced increase in molar volume of the activated state. On the other hand, secondary and tertiary peroxyesters undergo almost concerted bond scission with the immediate production of the linear CO_2 molecule. This gives rise to only a weak increase in molar volume of the activated state, even though two bonds are broken.

Rate coefficients for decomposition of aliphatic *tert*-amyl peroxyesters are given by

$$k_{\text{obs}}(p, T) = A \exp \left(\frac{E_A(0 \text{ bar}) + \Delta V^\ddagger p}{RT} \right) \quad (47)$$

with values of the parameters A , $E_A(0 \text{ bar})$, and $\Delta V^\ddagger$ as listed in Table 1.⁷⁵ Expressions for $k_{\text{obs}}(p, T)$ for *tert*-butyl peroxyesters are also available.⁷⁴

3.2 Initiator Efficiency

The mechanism of the primary peroxyester dissociation event is of relevance for initiator efficiency. In the case of concerted two-bond scission, the primary

radical fragments from decomposition may react with each other, by combination or disproportionation, within the solvent cage. These follow-up reactions reduce radical concentration and thus lower the initiator efficiency. In case of single-bond scission, combination of the primary fragments from peroxyester decomposition recovers the initiator, which may dissociate again to produce growing radicals. It is for this reason that the initiator efficiency of

primary peroxyesters is above that of secondary and tertiary peroxyesters.

Despite their lower efficiency, secondary and tertiary peroxyesters are widely used initiators, as they decompose much faster and thus allow radical production at lower temperatures. As monomer conversion is associated with a significant enhancement of temperature—in ethylene high-pressure polymerization amounting to about 11 °C per 1% conversion under adiabatic conditions—it is important to have an initiation strategy that delivers radicals at a practicable rate over a wide temperature range if one is to attain high monomer conversion in technical polymerization processes. In ethylene polymerizations, either mixtures—so-called cocktails—of initiators are applied or a high-temperature initiator is fed at the later stages of the tubular reactor.

The kinetically relevant quantity for modeling initiation in radical polymerization is R_i , which is the rate at which primary initiator-derived radicals add to monomer and thus start chain growth (Section 2.1). R_i is given by (8) for monofunctional peroxides; for bifunctional initiators, this simple expression is multiplied by 2, for trifunctional by 3, and so on. By definition, f is in the range

Figure 16 Arrhenius plot of reduced peroxide-induced monomer conversion Δx_r for ethylene polymerization initiated by di-*tert*-butyl peroxide and carried out at 2000 bar in the CSTR of a mini-plant device (see text).⁷⁶

from zero to unity. The fraction $(1 - f)$ refers to radicals that are consumed in side reactions other than recombination back to the initiator molecule.

Because of its enormous technical relevance, initiator efficiency has been studied in quite some detail for ethylene high-pressure polymerizations with initiation by a wide variety of organic peroxyesters.⁷⁶ Determination of f has been carried out via the quantity “reduced peroxide-induced monomer conversion” Δx_r .⁷⁷ Δx_r has been measured under stationary conditions in a continuously stirred tank reactor (CSTR). The quantity Δx_r is related to the rate coefficients of propagation k_p and termination k_t , to CSTR residence time τ , and to initiator efficiency f , via

$$\Delta x_r = \frac{\Delta x}{(c_{I,dec})^{0.5}} = \frac{k_p}{k_t^{0.5}} f^{0.5} \tau^{0.5} \quad (48)$$

$c_{I,dec}$ is the difference between c_I of the mixture prior to entering the CSTR and the actual c_I in the CSTR.

To avoid uncertainties that may result from the imprecise knowledge of k_p and k_t at polymerization conditions, it is recommendable to use (48) for f estimation by comparison with Δx_r measured for a reference initiator of known f under otherwise identical polymerization conditions, i.e., the same k_p , k_t , and τ .⁷⁷ Shown in Figure 16 is an Arrhenius plot of Δx_r for ethylene polymerizations at 2000 bar initiated by DTBP (Section 1.2). For this system,

f_{DTBP} is close to unity.⁷⁷ Therefore this system may be used to determine f of an arbitrary peroxyester: one compares the measured Δx_r values for the initiator under investigation and for DTBP under otherwise identical reaction conditions, and then via the known decomposition rate coefficients of the two initiators (which are involved in determining $c_{I,dec}$) one obtains the efficiency f for the initiator of interest.

The initiator efficiencies of 15 peroxides⁷³ are collated in Table 2.⁷⁶ Both alkyl groups R and R* of the *tert*-alkyl peroxyesters R-(CO)-O-O-C(CH₃)₂-R* (Figure 13) have been varied. The efficiency values of the peroxyesters under investigation are in the range $0.4 < f < 0.9$. The only previous literature values are for TBPEH and TBPP, for which Luft and coworkers^{78,79} found f_{TBPEH} to be above f_{TBPP} for ethylene polymerizations at 1700 bar. This is consistent with the numbers in Table 2 and with results reported by van der Molen *et al.*⁸⁰

To visualize the dependence of initiator efficiency on the type of peroxyester R group, f values of the five *tert*-butyl peroxyesters in Table 2 are plotted in Figure 17. Clearly, the size of f depends on whether the carbon atom in the α position to the carbonyl group is primary, secondary or tertiary. In passing from primary to tertiary peroxyesters, the initiator efficiency clearly decreases, but at the same time is essentially independent of the size of R. As a second piece of information, Figure 17 indicates that

f does not significantly depend on polymerization temperature. This finding may be understood as a consequence of f being determined by fast in-cage radical–radical processes.

With respect to initiator efficiency, it is of primary importance whether successive β -scission of primary radical species from initiator decomposition occurs within the short time interval, of about 1 ns duration, during which the radicals $R^*C(CH_3)_2O^*$ and $RCOO^*$ remain caged together. The two dominant follow-up reactions are decarboxylation of $RCOO^*$ (giving R^* and CO_2) and “deacetonization” of $R^*-C(CH_3)_2O^*$ (giving acetone and R^* radical). Both of these are β -scission reactions. With primary peroxyesters, for example, *tert*-butyl peroxyacetate, decarboxylation is too slow to occur to a large extent on the nanosecond timescale. On the other hand, the lower energy of tertiary radicals, for example, of *tert*-butyl, makes β -scission processes leading to *tert*-butyl radicals very fast, as with peroxy-pivalates. Any subsequent in-cage loss of radicals results in a lowering of initiator efficiency. This is pronounced in the case that the *tert*-butyl radical arises while highly reactive oxygen-centred radicals are simultaneously present. This situation may occur with the decompositions of rather dissimilar peroxyesters, as is illustrated in Figure 18, which takes tetramethylpropyl peroxyacetate and *tert*-butyl peroxy-pivalate as examples. With both peroxyesters, a *tert*-butyl radical is rapidly formed by deacetonization and decarboxylation, respectively. It then reacts with the other primary radical, which is oxygen-centred, via very fast disproportionation, resulting in lowered f .

Figure 17 Initiator efficiency f of *tert*-butyl peroxyesters in high-pressure ethylene polymerization at 2000 bar. Abbreviations for initiators are as in Table 2. The upper, middle, and lower lines indicate the arithmetic mean values of f for primary, secondary, and tertiary peroxyesters, respectively. [Reproduced from Ref. 76. © Wiley-VCH Verlag GmbH & Co. KGaA, 2007.]

Figure 18 Decomposition scheme for tetramethylpropyl peroxyacetate (TMPPA, left) and *tert*-butyl peroxyvalate (TBPP, right), showing irrecoverable loss of primary radicals, meaning initiator efficiency is low.

Density functional theory (DFT) calculations in conjunction with unimolecular rate theory support the findings for the dependence of β -scission rate coefficient k_β on the type of R-substituent.⁸¹ In passing from the *tert*-butoxy radical to the 1,1,2,2-tetramethylpropyloxy radical, k_β increases by about four orders of magnitude. These results from DFT calculation indicate that deacetonization occurs as an in-cage process with 1,1,2,2-tetramethylpropyloxy radicals, whereas with *tert*-butoxy, *tert*-amyloxy, and 1,1,3,3-tetramethylbutyloxy radicals this reaction most likely takes place out of the cage.

As well as variation from initiator to initiator, f also depends on conversion, as outlined in Section 2.2.3. Unfortunately, this important variation has been measured only very occasionally, most notably by quantitative IR³⁶ and NMR³⁷ spectroscopy, which may be used to monitor the appearance of end groups vis-à-vis side products from the initiator.

3.3 Photoinitiation

It is beyond the scope of this section to describe photoinitiation in any detail. However, a short

comment appears to be appropriate, as a variety of laser-induced techniques have become of pivotal importance for detailed investigations into rate coefficients of radical polymerization (Section 2.5). 2,2-Dimethoxy-2-phenyl acetophenone (DMPA) and benzoin have frequently been used as photoinitiator in PLP experiments. A problem with these initiators is that one fragment is resonance-stabilized—as shown in Figure 19 for DMPA—and thus is not prone to start propagation. Not only does this result in low efficiency (i.e., wasted initiator) but it may lead to different kinetics. For example, in SP PLP experiments to investigate chain-length-dependent termination (Section 2.5.1), the proportionality between radical size and time after applying the laser is affected, resulting in highly unusual $c_M(t)$ traces.⁸²

In view of this situation, α -methyl-4(methylmercapto)- α -morpholinopropiophenone (MMMP) has been used as a more ideal photoinitiator.^{83,84} As shown in Figure 19, neither of the primary radicals from its photochemical decomposition is resonance-stabilized, and therefore they both rapidly add to monomer.

Figure 19 Photoinduced decomposition of 2,2-dimethoxy-2-phenyl acetophenone (DMPA; top portion of scheme) and α -methyl-4(methylmercapto)- α -morpholinopropiophenone (MMMP; bottom). As shown, the acetal fragment from DMPA is resonance stabilized. Therefore it adds to monomer relatively slowly.

4 PROPAGATION

The addition of monomer to a radical species is considered to be a chemically controlled process, which is controlled by electronic, steric, and polar effects. The primary addition step, in which an initiator-derived radical species adds to a monomer molecule, differs from subsequent addition reactions in which monomer adds to monomer-specific radicals giving rise to radical chain extension by one monomer unit. With the exception of the early such addition steps of monomer to a monomer-specific radical, no chain-length dependence is expected to occur with propagation reactions.¹⁵ Propagation appears to be rather simple in that a radical species adds to monomer producing the same type of radical. Nevertheless, attempts to estimate accurate propagation rate coefficients from quantum chemical *ab initio* methods have not been overly successful so far, even if such calculations do detect the major trends. As a consequence, precise propagation rate coefficients must still be experimentally determined. Measurements are particularly important for propagation in polar solvents, as the environment of the reacting species is not easily implemented into *ab initio* calculations. Another difficulty is

associated with the occurrence of different types of radicals, for example, of secondary and tertiary radicals in the case of acrylate polymerization, the concentrations of which are not readily accessible from quantum chemical calculations. In view of all this, this section will focus on what has been learned about propagation from experimental data.

4.1 Measurement of Propagation Rate Coefficients

All the understanding of k_p that is presented here stems from measurement of values via the MP PLP technique of Section 2.5.2, which is also referred to as the PLP SEC method, because molar-mass analysis of the polymeric product from multiple pulsing has overwhelmingly been carried out by SEC (notwithstanding the existence of several successful studies using MS instead). It is impossible to overstate how much this technique has advanced the entire field of RP kinetics. Prior to its advent, the principal method of determining k_p was by combining a $k_p/\langle k_t \rangle$ measurement from NSSP with a $k_p/\langle k_t \rangle^{0.5}$ measurement from SSP (Section 2.5.1). Not only was this experimentally

laborious (NSSP methods are not easy³⁰), but CLDT makes it impossible to have that $\langle k_t \rangle$ is the same in these two different types of experiment.¹⁶ Simulations have shown that this leads to large errors in both k_p and $\langle k_t \rangle$,⁸⁵ explaining why prior to MP PLP there was so much scatter in the literature data for k_p . There do exist other solutions to this difficulty, for example use of an emulsion polymerization technique⁸⁶ or an EPR technique⁸⁷ for measuring k_p . However, the former may only be used for an extremely limited number of monomers, while the latter may be subject to both random and systematic error.⁶⁵ Further, neither is as easy or as intuitive as the MP PLP technique. Thus to all intents and purposes, one may say that the latter should always be used to measure k_p .

4.2 Understanding Propagation Rate Coefficients

The MP PLP technique has been applied to the study of k_p for a wide variety of monomers.^{66,67} Many of these values have been critically evaluated by the IUPAC Subcommittee on Modeling of Polymerization Kinetics and Processes.⁸⁸ So far, this IUPAC subcommittee has collated reliable k_p for styrene,⁶⁵ MMA,⁸⁹ other alkyl methacrylates,⁹⁰ methacrylates with cyclic ester groups,⁹¹ *n*-butyl acrylate (BA),⁹² and methacrylic acid (MAA) in aqueous solution.⁹³ The reader is referred to these works for the resulting Arrhenius expressions. The data demonstrate a pronounced family-type behavior for methacrylates and acrylates, with the activation energy of k_p being more or less identical within each family. Therefore the variations in k_p from monomer to monomer within each family are essentially due to changes in the pre-exponential factor of the Arrhenius equation.

Because of chemical control, k_p is considered to be independent of the degree of monomer conversion, unless conversions are reached where the system becomes glassy, at which point k_p switches to being diffusion-controlled, and therefore starts varying with viscosity.³⁵ Moreover, k_p in solution should not be strongly affected by the monomer content. To clarify whether this latter assumption is valid, it seemed worthwhile to investigate systems with strong intermolecular interactions, for example, hydrogen-bonded monomers, such as acrylic acid,⁹⁴

Figure 20 Variation of the propagation rate coefficient k_p of methacrylic acid with MAA concentration c_{MAA} in aqueous solution at 25 °C.⁹⁵

MAA,^{93,95} *N*-vinyl pyrrolidone,⁹⁶ and *N*-vinyl formamide⁹⁷ in aqueous solution.

In what follows, the aspects of k_p variation in aqueous solution are illustrated taking MAA as an example. The MAA system is of particular interest for studies of solvent effects on k_p , as PLP SEC experiments may be carried out over the entire concentration range from 1% up to bulk MAA. An enormous reduction in k_p upon increasing MAA concentration occurs, as is illustrated by the k_p versus c_{MAA} plot in Figure 20.

The significant lowering of k_p with MAA content is essentially, if not entirely, due to a decrease of the Arrhenius pre-exponential factor $A(k_p)$, whereas the activation energy $E_A(k_p)$ is more or less insensitive toward c_{MAA} .⁹⁵ This pronounced change is a genuine kinetic effect, which may be adequately understood in terms of transition state (TS) theory. As Heuts *et al.* pointed out,⁹⁸ the size of $A(k_p)$ is largely governed by the degree to which the internal rotations of the TS for propagation are hindered. This fundamental kinetic effect is associated with the fact that three transitional degrees of freedom are replaced by internal rotational or hindered vibrational degrees of freedom upon formation of the TS structure from a radical and a monomer molecule. In the event of severe hindrance of these internal motions, the associated

Figure 21 Illustration of the transition state (TS) structure for propagation in methacrylic acid polymerization. The gray areas indicate the surrounding molecular environment. In bulk polymerization, these areas consist entirely of MAA molecules. In aqueous solution, they are made up of water and MAA. The arrows indicate internal rotational motions associated with the formation of the TS structure from a radical (top left) and a monomer molecule (bottom right). Clearly, these motions are affected by the gray areas.

entropy penalty results in a significant lowering of the pre-exponential factor, and hence of k_p .

Illustrated in Figure 21 is the TS structure for MAA propagation. It has been drawn according to the figure given by Heuts *et al.* for ethylene homopolymerization.⁹⁸ The upper left part shows the terminal unit of an MAA macroradical. Given in the lower right part of Figure 21 is the MAA molecule that adds to the macroradical. The dashed line represents the bond that is formed in the TS structure. The arrows indicate the three degrees of hindered internal rotational-type motion associated with TS formation. The hindrance of internal rotational mobility may result from intramolecular effects, for example, ones induced by substituents on the backbone, and/or from intermolecular effects, for example, polar or hydrogen-bonding interactions. Intermolecular effects play a dominant role in the case of MAA propagation because of the strong hydrogen bonds between carboxylic acid moieties. Intramolecular effects should not be responsible for the major changes in hindrance to internal rotation upon varying the MAA content, as these interactions do not affect the substitution at the polymeric backbone.

Upon passing from polymerization in dilute aqueous solution to MAA bulk polymerization, the essential change in molecular environment consists in the gradual replacement of water molecules by MAA molecules. Toward higher MAA content, the particularly strong hydrogen-bonded interactions

between carboxylic acid groups become dominant. The formation of intermolecular cyclic dimeric COOH structures induces a larger friction than that associated with the interaction of the TS structure with water molecules. That the intermolecular interactions influence k_p may also be demonstrated by adding sodium hydroxide to the solution of non-ionized MAA. In aqueous solution at 5 wt.% MAA, k_p is lowered by about one order of magnitude in passing from the non-ionized to the fully ionized monomer.⁹⁹ Of course, increasing the degree of ionization acts to enhance the intermolecular interactions.

That $A(k_p)$ is correlated with the hindrance to chain mobility of the transition structure may also be seen from a comparison of the $A(k_p)$ values for MAA, MMA, and methyl acrylate (MA) bulk homopolymerizations. These $A(k_p)$ values read: $0.38 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for MAA,⁹⁵ $2.67 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ MMA,⁸⁹ and $16.6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ MA.⁶⁶ With respect to $A(k_p)$ of MMA, the pre-exponential of MAA is lower by about one order of magnitude because of the hindrance provided by the strong hydrogen bonds. The $A(k_p)$ value of MA, on the other hand, is significantly higher than with MMA due to the favorable effect on internal rotational mobility that results from replacing the methyl group at every second carbon atom of the backbone with a hydrogen atom.¹⁰⁰

The studies of k_p of MAA in aqueous solution are of general importance in making clear that, contrary to the general expectation, the propagation rate coefficient may be strongly solvent-dependent. The explanation behind the large effect is a genuine kinetic one, which indicates that such effects may occur with all systems, although of course to widely differing extents. The strong solvent effect on k_p seen in aqueous solution of MAA is due to the significant difference of intermolecular interactions of the TS structure with an environment essentially consisting of water molecules and an environment consisting of MAA molecules. Thus clearly different degrees of friction to internal rotation occur in the two environments, giving rise to largely different pre-exponentials $A(k_p)$. That k_p has been considered for a long time to be insensitive to solvent content is due to the fact that mostly solvents have been investigated that, with respect to polarity, are similar to the monomer. With monomer and solvent having (almost) the same polarity, kinetic theory predicts at most small differences

between bulk and solution $A(k_p)$. It should also be mentioned that the advent of PLP SEC has enabled k_p data to be collected systematically and accurately, elements that previously were often lacking from studies, leading to the obscuring of solvent effects.

It needs to be kept in mind that bulk polymerization may be considered as a solution polymerization with monomer acting as the solvent. An immediate consequence of this latter insight is that k_p should not depend on the degree of conversion in bulk polymerizations, as the molecular environment of the TS structure remains the same throughout the polymerization to higher conversion: the radical site is embedded somewhere within a monomer-swollen macroradical coil and will not see other polymer, with the exception of oligomeric material or situations where the coils are interpenetrating. However, this insensitivity of k_p to monomer conversion must not hold in solution polymerizations. This has been demonstrated for MAA polymerizations in aqueous solution,¹⁰¹ where k_p was observed to increase toward higher degrees of monomer conversion. This effect may also be adequately understood in terms of the genuine kinetic argument about control of $A(k_p)$ through the friction experienced by the TS structure. During MAA solution polymerization, MAA molecules in the vicinity of the TS structure, for example, within the coiled macroradical, are replaced by water molecules, thus lowering the friction to internal rotation and enhancing $A(k_p)$, and

hence increasing k_p . This change occurs at constant overall density of COOH moieties, as the polymeric MAA segments produced during reaction do not affect the molecular environment at the radical site, which is essentially given by the ratio of monomeric MAA to water.

The insight into the effect of inter- and intramolecular interactions on $A(k_p)$ and thus on k_p helps us to understand several other seemingly unusual types of k_p behavior, for example, the variation with alkyl ester size of (meth)acrylate k_p . This is shown in Figure 22, which presents data for bulk polymerization⁶⁶ and toluene-solution polymerization¹⁰² of acrylates. Ester size increases from left to right, with MA and dodecyl acrylate (DA) being the smallest and largest family members, respectively. Whereas bulk k_p is enhanced toward larger ester size, the toluene-solution values exhibit some lowering of k_p . The trend seen with acrylate bulk k_p is also observed within the methacrylate family.^{66,90}

These effects may be rationalized on the basis of the new insight into the impact of intermolecular interactions on $A(k_p)$. The increase in bulk k_p upon passing from MA to DA is understood as a result of enhanced shielding of polar groups of the TS structure by longer nonpolar alkyl groups. As a consequence, the dipolar interactions become weaker in passing from MA to DA. This weakening is accompanied by reduced friction to internal rotations and thus an increase in k_p . Within the

Figure 22 Comparison of propagation rate coefficients k_p for a series of alkyl acrylates in bulk (triangles) and in toluene solution¹⁰² (circles; 1.5 to 4.7 M) at 20 °C. The acronyms refer to acrylates with methyl (MA), ethyl (EA), *tert*-butyl (*t*-BA), *iso*-butyl (*i*-BA), *n*-butyl (*n*-BA), 2-ethylhexyl (EHA), nonyl (NA), and dodecyl (DA) side groups. [Reproduced from Ref. 100. © Wiley-VCH Verlag GmbH & Co. KGaA, 2009.]

solution experiments, the molecular environment varies to a much weaker extent, as toluene acts as the solvent with all the acrylates under investigation. Thus no major change in friction toward rotational mobility of the TS is expected to occur. The weak decrease in k_p that is seen for the toluene-solution experiments toward larger size of the alkyl group is possibly due to some minor enhancement of the shielding of the radical site.

Assigning changes in k_p to effects on internal rotational mobility of the TS structure may also explain the solvent dependence of k_p of MMA and *iso*-bornyl methacrylate.¹⁰³ As compared with bulk k_p , the k_p value in solution increases in solvents with molar volume exceeding that of the pure monomer and vice versa. Larger solvent molecules allow for enhanced rotational mobility than do smaller solvent molecules, which better fill the voids between molecules.¹⁰⁰

Another important point is that the idea of hindered TS rotations as an explanation for k_p behavior was first put forward in relation to the chain-length dependence of propagation at small chain lengths.⁹⁸ So this is another k_p phenomenon that is also explainable within the present framework.¹⁵

Finally, it goes without saying that $E_A(k_p)$ is tremendously important in determining the value of k_p . The discussion here has focused on *trends* in k_p

for cases where E_A is the same. Such family-type behavior—groups of monomers for which $E_A(k_p)$ is essentially the same—is turning out to be remarkably widespread.

4.3 Propagation in Copolymerization

The discussion above has considered only *homopropagation* data. As explained in Section 2.4, these are also involved in *copolymerization*. Additionally, *reactivity ratios* are central. Since the principles presented above are perfectly general, they should also hold for such copolymerization reactivity ratios. Indeed, in what follows it will be seen that these show some peculiarities that are easily understood via the above entropy arguments concerning $A(k_p)$.

4.3.1 Monomer Reactivity Ratios

These are the r 's of (37). Extensive compilations of such values are available.¹⁰⁴ As explained in Section 2.4.1, these values are most commonly obtained by fitting of copolymer composition data. An example has already been seen in Figure 8. A further example is presented in Figure 23. It shows

Figure 23 Mole fraction F_{mac} of methacrylate in copolymer as a function of mole fraction f_{mac} of methacrylate in monomer feed for several acrylate (“ac”)/methacrylate bulk systems at 1000 bar: DA/DMA (40 °C, squares), MA/DMA (40 °C, diamonds), DA/MMA (23 °C, full triangles; 40 °C, open triangles), and MA/MMA (23 °C, full circles). Line: best fit of (35). Inset: 95% confidence interval for the best-fit reactivity ratios r_{ac} and r_{mac} . [Reproduced from Ref. 106. © Wiley-VCH Verlag GmbH & Co. KGaA, 2007.]

the composition data that have been taken at temperatures from 23 to 40 °C for four different alkyl acrylate/alkyl methacrylate pairs,^{105,106} these being a small acrylate, MA, with either a small methacrylate (methyl, MMA) or a large methacrylate (dodecyl, DMA), and a large acrylate, DA, with either MMA or DMA. It is clear that the compositions of the four copolymerization systems, namely, MA/MMA, MA/DMA, DA/MMA, and DA/DMA, may be adequately represented by a single pair of acrylate and methacrylate reactivity ratios r_{ac} and r_{mac} . This is one of several important points about reactivity ratios that are brought to light by this figure and which will now be outlined.

1. The r values for a particular monomer pair may generally be used over a range of temperatures. Coote *et al.* showed that styrene/MMA data for 20–60 °C may all be fitted by the one pair of r values.¹⁰⁷ Hutchinson *et al.* have established this even more extensively, as follows: styrene/*n*-butyl methacrylate 50–150 °C,¹⁰⁸ styrene/glycidyl methacrylate 50–140 °C,¹⁰⁹ and styrene/2-hydroxyethyl methacrylate 50–120 °C.¹¹⁰ So it would appear that to good approximation one may regard monomer reactivity ratios as being independent of temperature. This may come as a surprise, as r values are ratios of k_p values, and homopolymerization k_p values are known to vary significantly with temperature.

This result may be understood as follows: Consider styrene/MMA. For bulk styrene, $E_A(k_p) = 32.5 \text{ kJ mol}^{-1}$,⁶⁵ for bulk MMA, $E_A(k_p) = 22.4 \text{ kJ mol}^{-1}$.⁸⁹ So for a cross-propagation reaction in this system—involving one type of radical, the other type of monomer—one may expect that $E_A(k_p)$ is *approximately* halfway between these two values. Referring to how reactivity ratios are defined, this means that $E_A(r_{sty}) \approx 5 \text{ kJ mol}^{-1}$ and $E_A(r_{MMA}) \approx -5 \text{ kJ mol}^{-1}$. As is shown in Figure 24, an E_A of this size results in a rate parameter (the temperature-variation of which is entirely captured by k/A , the quantity presented) having only a relatively small variation over 0–100 °C, which may be considered a large temperature range for composition measurements. Often, the difference in homopropagation E_A will be smaller than in the example here, leading to even smaller $|E_A(r)|$. Given this, it is

Figure 24 Variation of $k/A = \exp(-E_A/[RT])$, where k is rate coefficient and A pre-exponential factor, for different values of activation energy, E_A , over the temperature range $0 \leq \theta/^\circ\text{C} \leq 100$.

clear why data may be fitted with r values that are independent of temperature: even though $E_A(r) \neq 0$, the actual $E_A(r)$ values are too small for r to change measurably over most practical temperature ranges. Another factor in explaining the apparent lack of variation of r values with temperature is that composition data is relatively insensitive to changes in r , as illustrated in Figure 8.

Lest there be any any confusion, it needs to be stressed that values of r do vary with temperature, and we are not suggesting otherwise. For example, the activation energy for the ethylene reactivity ratio $E_A(r_E)$ has been measured in copolymerization with acrylates,¹¹¹ methacrylates,¹¹² and (meth)acrylic acid,¹¹³ and was found to be remarkably constant—approximately 12 kJ mol^{-1} —from system to system.¹¹³ What enabled these values (and those of the comonomers) to be determined is that they are relatively large and a considerable temperature range was possible, because ethylene is polymerized at high temperature. However, for most systems $E_A(r)$ is smaller and/or the temperature variation is not as great, meaning that data can often be adequately described with temperature-independent values of r .

2. Buback *et al.* examined the rate coefficient data from the literature for small-molecule analogs of acrylate and methacrylate radicals adding to MA and MMA. They showed that this data

leads to $r_{ac} = 0.38$ and $r_{mac} = 3.23$.¹⁰⁵ All things considered, these values are remarkably close to the best-fit macroradical values of Figure 23. Similar close agreement between r from model and corresponding polymer systems has also been observed by other workers. Thus one may be confident that r values from fitting composition data do actually correspond to the physical truth for copolymerization propagation rate coefficients.

3. A third important finding from Figure 23 is that both reactivity ratios r_{ac} and r_{mac} are insensitive to the type of monomer that is added to a particular chain end: for example, r_{MA} appears to be the same in both MA/MMA and MA/DMA copolymerization. Hutchinson *et al.* found the same for styrene/*n*-alkyl methacrylate systems;¹¹⁰ that is, the one set of r values could be used to describe all such data. To understand this remarkable phenomenon, consider the case of r_{MA} in Figure 23. Its constancy means that $k_{pMA,MMA} \approx k_{pMA,DMA}$. Inspection of Figure 21 indicates why this should indeed be the case. The region of the TS structure that controls the extent of hindrance to internal rotation encompasses the radical chain end (probably including the penultimate segment) and the $CH_2=C$ part of the monomer. The specific alkyl ester group is probably too far off this kinetically relevant area to significantly affect $k_{pMA,mac}$, where “mac” refers to an arbitrary alkyl methacrylate. The same type of argument should explain the similarity of the r_{mac} values, and indeed it should hold wherever comonomer is only varied within a monomer family.
4. Finally, as is invariably the case with composition data, the results of Figure 23 may be perfectly adequately fitted with just r_1 and r_2 , which suggests that $r_{11} = r_{21}$ and $r_{22} = r_{12}$ to good approximation (i.e., the “IPM” of Section 2.4.2). The reason why this simplification mostly holds is probably that $r_{11} = k_{p111}/k_{p112}$ and $r_{21} = k_{p211}/k_{p212}$, for example, are ratios of propagation rate coefficients that apply to radicals with identical terminal and penultimate units. The ratioing procedure seems to eliminate the impact of the penultimate unit on the rate coefficients.⁵² The same argument may be used to explain why r_{22} is close to r_{12} .

In summary, a pair of r_a values: is generally adequate to describe composition data without needing to invoke penultimate unit effects (point 4 above); to good approximation will hold independent of temperature (point 1); and also to good approximation will hold for other monomer pairs where monomer variation is within the same family only (point 3). Given the undoubted complexity of copolymerization k_p values, these are remarkable and highly useful simplifications. Further, these findings are surprising given the decades of effort that have gone into devising complex schemes for estimating r_a values that are implied to be highly variable.

4.3.2 Radical Reactivity Ratios

These are the s 's of (40). As explained in Section 2.4.2, their values are obtained by fitting of copolymer k_p data. The best available compilation of these values is that of a recent work.¹¹⁴ An aim of this work was to objectively assess the proposal that¹¹⁵

$$s_1 s_2 = r_1 r_2 \quad (49)$$

Fukuda *et al.* derived this relationship solely on *enthalpic (energetic)* grounds.¹¹⁵

Equation (49) has infused much of the work on copolymerization k_p over the last two decades. Quite often this equation seems to hold;^{49,116} however, it has never been clear whether this is for genuine mechanistic reasons or is simply a consequence of large joint-confidence intervals for s_1 and s_2 .⁵⁵ As has recently been summarized,⁵ gradually the evidence against (49) has mounted, culminating in the meta-analysis of Ref. 114. Points were found to be scattered almost randomly on the plot of $s_1 s_2$ versus $r_1 r_2$ from this work, leading the authors to conclude “[$s_1 s_2 = r_1 r_2$] is obeyed in some rare cases only ... This means, rather unfortunately, that this theorem is of little help in reducing the number of parameters.”¹¹⁴

In hindsight it is not surprising that (49) is unlikely to be the physical truth. Because r values involve variation of the *monomer*, it is clear that they must entail enthalpic considerations. However, s values involve variation of only the penultimate unit of the radical. Not only does it seem obvious

Figure 25 Propagation rate coefficient $k_{p,copo}$ as a function of the methacrylate mole fraction f_{mac} of MA/MMA and MA/DMA copolymerizations at 1000 bar. The dotted lines are the respective TM predictions with $r_{mac} = 2.55$ and $r_{ac} = 0.29$, while the full lines are IPM best fits. [Reproduced from Ref. 106. © Wiley-VCH Verlag GmbH & Co. KGaA, 2007.]

that such substitution should result in *steric* effects, but it also seems likely that a penultimate unit should have only a small effect on the energy of the associated radical, because the two entities are several bonds apart.⁵²

Where does this leave understanding of s values? In what follows we summarize the findings of the recent acrylate/methacrylate study that has already been mentioned.¹⁰⁶

The almost identical composition behavior of the four acrylate/methacrylate systems (Figure 23) may suggest that also the propagation rate coefficients behave similarly. Experimental values of copolymerization k_p for MA/MMA and MA/DMA are plotted in Figure 25.¹⁰⁶ The full lines represent best fits with the IPM (Section 2.4.2), whereas the dotted lines are calculated from the TM with $r_{ac} = 0.29$ and $r_{mac} = 2.55$, these being the values from composition analysis (Figure 23). The remarkable observation from Figure 25 is that the TM affords an impressive prediction of measured k_p for both MA-containing copolymerization systems. Particularly surprising is the excellent quality of the fit in the case that alkyl ester sizes are dissimilar, i.e., with the MA/DMA system, where the TM is capable of simultaneously representing copolymer composition and copolymer propagation behavior with the same pair of reactivity ratio numbers.

The behavior of MA/DMA raised interest in checking whether the same simple behavior occurs with the complementary system, namely, DA/MMA. That this is definitely not the case is immediately clear from the k_p data presented in Figure 26.¹⁰⁶ The TM with $r_{ac} = 0.29$ and $r_{mac} = 2.55$ completely fails to reproduce the experimental data. It should, however, be noted that the IPM also does no satisfactory job. A better representation of k_p for DA/MMA is achieved by fitting the data to the TM expression for k_p . This results in a different pair of reactivity ratios: $r_{DA} = 0.30$, $r_{MMA} = 0.64$. These are obviously no satisfactory values, as they predict there is an azeotropic composition ($F_{mac} = f_{mac}$) for this system; however, Figure 23 shows this definitely is not the case (cf. Figure 8). Moreover, using two sets of reactivity ratios, one for composition and one for propagation kinetics, is obviously no satisfactory situation. The disagreement of the pairs of reactivity ratio data clearly indicates the need for applying a PM.

To keep the number of adjustable parameters low, a simplified IPM model may be used that adopts the reactivity ratio data from composition analysis and assumes the product of the two radical reactivity ratios to be unity, that is, $s_{ac}s_{mac} = 1$. This relationship may be justified using TS theory and assuming that only entropic effects

Figure 26 Propagation rate coefficient $k_{p, \text{copo}}$ for the DA/MMA system at 23 °C and 1000 bar plotted as a function of methacrylate mole fraction f_{mac} of the monomer mixture. The dotted line is the TM prediction with $r_{\text{mac}} = 2.55$ and $r_{\text{ac}} = 0.29$; the full line is from IPM fitting; and the dashed line is from TM fitting of $k_{p, \text{copo}}$ alone, which results in the reactivity ratios $r_{\text{mac}} = 0.64$ and $r_{\text{ac}} = 0.30$. [Reproduced from Ref. 106. © Wiley-VCH Verlag GmbH & Co. KGaA, 2007.]

are significant in determining s values.^{52,100,106} It leaves s_{ac} as the single parameter to be varied in fitting copolymerization k_p data. For MA/DMA, this yields $s_{\text{MA}} = 0.99$ and $s_{\text{DMA}} = 1.01$,¹⁰⁶ which reflects the almost perfect TM behavior (Figure 25). Similar is the case for MA/MMA. For DA/DMA, the k_p data is well described but the s values deviate significantly from unity: $s_{\text{DA}} = 0.34$ and $s_{\text{DMA}} = 2.97$.¹⁰⁶ For DA/MMA, the deviations are even greater— $s_{\text{DA}} = 0.09$ and $s_{\text{MMA}} = 11.32$ ¹⁰⁶—and the fit is lacking, as is implicit in Figure 26. This suggests that for DA/MMA even the PM may be insufficient and pen-penultimate segments should be included into the modeling. In all of these examples, $r_1 r_2 \approx s_1 s_2 = 1$, even though one may be sceptical of the grounds for (49). It is therefore significant that $s_1 s_2 = 1$ has recently been shown to work well for several styrene/methacrylate systems where $r_1 r_2$ is considerably less than 1.⁵

As well as the value of the product $s_1 s_2$, there is also the issue of the meaning of the individual s_a values. Here, the argument of hindrance to internal mobility has again been invoked for acrylate/methacrylate systems.^{100,106} It is especially relevant in considering MA/DMA and DA/MMA, where the enormous differences in propagation behavior are not easily understood. Two contributions to hindrance of rotational mobility may be

distinguished: (i) an intermolecular mobility term, *interMT*, associated with shielding of dipolar intermolecular interactions by alkyl ester groups; and (ii) an intramolecular mobility term, *intraMT*, associated with the type of penultimate unit. Replacing a methacrylate penultimate segment by an acrylate segment has a favorable intramolecular effect on chain-end mobility and vice versa. The *intraMT* and *interMT* contributions have been shown to explain at a qualitative level all the s_{ac} and s_{mac} values presented above.^{100,106} Therefore this model shows promise for wider understanding of copolymerization k_p .

Indeed, the insight that hindrance to internal rotational motion controls $A(k_p)$ has been shown in this section to help understand many aspects of homopropagation and copolymerization behavior that previously were not clear.

5 TERMINATION

5.1 Measurement of Termination Rate Coefficients

There are numerous methods for determining $\langle k_t \rangle$, far too many to cover here. Instead, the interested reader is referred to a comprehensive review on

this topic.³⁰ This number is considerably reduced when restricted to methods that shed light on CLDT, as is essential for mechanistic investigation of termination. Again, this topic has recently been thoroughly reviewed.¹⁸ What emerges from these two reviews is that SP PLP EPR, as outlined in Section 2.5.1, is the most powerful technique for determining $k_t^{i,i}$. The understanding of CLDT that is presented here stems largely from measurements made this way.

Mention should also be made of a simple technique for probing CLDT of long chains. Combining (17) and (30) results in^{24,40}

$$\langle k_t \rangle = k_t^{1,1} G(DP_n)^{-\alpha}, \text{ where} \\ G = \left[\Gamma \left(\frac{2}{2-\alpha} \right) \right]^{\alpha-2} \left(\frac{2}{2-\alpha} \frac{2}{1+\lambda} \right)^{\alpha} \quad (50)$$

Thus a plot of $\log \langle k_t \rangle$ versus $\log DP_n$ has slope $-\alpha$ and intercept $\log(Gk_t^{1,1})$. Under normal circumstances, $G \approx 1$, meaning that the intercept directly yields an approximate value of $k_t^{1,1}$. In this way, a series of experiments in which the rate of initiation, for example, is varied in order to vary the measured quantities of $\langle k_t \rangle$ and DP_n may be used to obtain α and $k_t^{1,1}$.¹⁸

5.2 Chain-Length Dependence at Low Conversion

The issue of CLDT has occupied minds for over 50 years.^{21,22} It is not a simple matter. Almost all experimental studies have concentrated on low-conversion conditions. Ultimately, the campaign has been successful, with essentially all of the significant advances having been made over the last 25 years. Recently, the topic was comprehensively reviewed.¹⁸ This section presents a brief summary of the essential findings and lines of thought.

Figure 27 shows $\langle k_t \rangle$ data for both bulk styrene¹¹⁷ and bulk MMA¹¹⁸ at low conversion. Clearly, there is a variation of $\langle k_t \rangle$ such that, as average chain size becomes smaller, termination becomes more rapid. This is consistent with intuition regarding CLDT. Quantitatively, these results are to be interpreted in the light of (50). From the slopes of the linear fits to the data, one obtains $\alpha \approx 0.16$, while from the intercepts it follows that $k_t^{1,1} \approx 10^8 \text{ M}^{-1} \text{ s}^{-1}$. Both

Figure 27 Termination rate coefficient $\langle k_t \rangle$ as a function of number-average degree of polymerization DP_n as measured using MP PLP at 25 °C for bulk styrene¹¹⁷ (circles) and bulk methyl methacrylate¹¹⁸ (squares). Lines: linear best fits to each dataset, with slope and intercept as displayed.

these values are typical of what has been found wherever *careful* studies of this nature have been carried out.¹⁸

Considering first the exponent for variation of $k_t^{i,i}$ with chain length, $\alpha \approx 0.16$ is exactly in agreement with what theory¹¹⁹ predicts for the case of segmental rearrangements upon coil overlap being the rate-determining step for termination. In other words, the middle step in Figure 28 sets the tone. It is stressed that this is established *only* for (relatively) long chains *only* in dilute solution conditions.

Figure 28 Depiction of the three mechanistic steps involved in the termination process. [Reprinted from Progress in Polymer Science, Vol. 34, C. Barner-Kowollik and G. T. Russell, Chain-length-dependent termination in radical polymerization: Subtle revolution in tackling a long-standing challenge, 1211–1259, Copyright (2009), with permission from Elsevier.]

Figure 29 Log-log plot of radical concentration in the form of $c_{R,0}/c_R - 1$ versus time t from an SP PLP EPR experiment with dodecyl methacrylate at 0 °C and low conversion. Points: experiment; line: integrated rate law for composite model⁵⁶ with $k_t^{1,1} = 1.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, $\alpha_S = 0.65$, $\alpha_L = 0.17$, and $i_c = 50$. [Reproduced from Ref. 120. © American Chemical Society, 2006.]

Turning now to the values of $k_t^{1,1}$ implied by Figure 27, two serious problems emerge:²⁴ (i) The distinction in Figure 28 between translational diffusion and segmental diffusion is one that does not exist for oligomers at the very least. In other words, for short chains it does not make sense to speak of diffusion upon overlap as being a separate and different diffusion step in the termination process. Thus there is no reason why $\alpha \approx 0.16$ should hold for all chain lengths right down to $i = 1$ and, indeed, the derivation of $\alpha = 0.16$ is clearly one predicated on macroradicals being long chains.¹¹⁹ Hence there is no reason to have confidence in extrapolating the linear fits of Figure 27 down to the size of monomeric radicals. (ii) In fact, the measured values of small-molecule termination rate coefficients show that $k_t^{1,1} \approx 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for monomers such as styrene and MMA.¹⁷ This is an order of magnitude higher than the intercepts of the fits of Figure 27. The only real way of explaining this is that CLDT must be considerably stronger (i.e., higher α) for short chains.

In view of the above situation, Smith *et al.* proposed what they termed the *composite model* for termination:²⁴

$$\begin{aligned} k_t^{i,i} &= k_t^{1,1} i^{-\alpha_S}, \quad i \leq i_c \\ k_t^{i,i} &= k_t^{1,1} (i_c)^{-\alpha_S + \alpha_L} i^{-\alpha_L}, \quad i > i_c \end{aligned} \quad (51)$$

The key feature of this model is that, at chain length i_c , there is a crossover from short-chain termination behavior with power-law exponent α_S , to long-chain behavior characterized by α_L . Note from the second line of (51) that an *apparent* $k_t^{1,1}$ of value $k_t^{1,1} (i_c)^{-\alpha_S + \alpha_L}$ will be returned by long-chain experiments. Since $\alpha_S > \alpha_L$, this explains why the intercepts of the linear fits of Figure 27 (i.e., the apparent values of $k_t^{1,1}$) are less than expected. By a happy coincidence, the SP PLP EPR method, with its unprecedented ability to probe the CLDT of short radicals, emerged⁵⁸ just after (51) was proposed. It was immediately found that SP PLP EPR data could only be explained by α being significantly different for short and long chains.⁵⁸ This is exemplified in Figure 29.¹²⁰

In a nice case of experiment–theory synergy, theory²⁴ was first of all needed to explain the unexpected⁵⁸ SP PLP EPR results, while since then the sheer volume of such results has served to reinforce the theory, for by now there have been many SP PLP EPR studies,¹⁹ all finding composite-model behavior along the lines of Figure 29. A pair of CLDT methods based on reversible addition–fragmentation (chain-)transfer (RAFT) polymerization¹²¹ (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and**

Applications) have also found such behavior across a variety of monomers.¹⁸ This behavior is as follows:¹⁸ (i) $\alpha_L \approx 0.2$, in agreement with long-chain studies (e.g., that of Figure 27) and theory;¹¹⁹ (ii) α_S is considerably greater than α_L , being in the range 0.5–0.65 for styrene and methacrylates. These values are remarkably consistent with oligomer diffusion data,^{122,123} suggesting that the rate of short-chain termination is simply controlled by center-of-mass diffusion (Figure 28); (iii) i_c ranges from 100 for MMA down to about 20 for some acrylates. All this is exactly as envisaged when the composite model was proposed.²⁴ For tables of values, the reader is referred to Ref. 18.

A feature of the already mentioned small-molecule termination rate coefficients from model systems is that they are in good agreement with the Smoluchowski equation.¹⁷ Applied to the monomeric radicals of RP systems, this equation reads

$$k_t^{1,1} = \frac{1}{4} 2\pi(D^1 + D^1)\sigma \quad (52)$$

Here, D^1 is monomer diffusion coefficient, σ is the radical–radical separation at which the chemical reaction of termination occurs (Figure 28), and the fraction accounts for spin multiplicity. From the Stokes–Einstein equation, one has $D^1 \sim (r_1\eta)^{-1}$, where η is viscosity and r_1 is the hydrodynamic radius of monomer. Therefore, one predicts that $k_t^{1,1}r_1\eta$ should be relatively constant as monomer, solvent, and temperature are varied, and that $E_a(k_t^{1,1}) \approx E_a(\eta^{-1})$. Barth *et al.* have shown that these predictions are obeyed by all SP PLP EPR data thus far gathered.^{19,59} It appears that $k_t^{1,1}$ often is as simple as (52).

All in all, it may be said that the current situation in regard to low-conversion termination is enormously pleasing and amounts to a remarkable success story from a troubled background.

5.3 Conversion Dependence of Termination Rate Coefficients

Dilute solution conditions prevail only for the first few percent conversion of a bulk polymerization. Therefore, one needs to know far more about termination than has been revealed in Section 5.2.

Figure 30 Variation of overall termination rate coefficient $\langle k_t \rangle$ with fractional conversion x of monomer into polymer for bulk polymerization of methyl methacrylate at ambient pressure and 0 °C¹²⁴ (filled circles; reprocessed values¹⁶) and 50 °C¹²⁵ (empty circles), and for DA at 1000 bar and 40 °C¹²⁶ (squares; reprocessed values⁶⁶).

Specifically, one is interested in the *entire* variation of $\langle k_t \rangle$ with conversion, a topic introduced in Section 2.2.3. This is especially important for the modeling of commercial processes. Figure 30 presents data for bulk MMA^{124,125} and bulk DA¹²⁶.

Considering first the MMA data, one sees that there is enormous variation of $\langle k_t \rangle$ across the span of conversion, with $\langle k_t \rangle$ dropping by over five orders of magnitude. Further, the decrease is irregular rather than constant. In particular, initially $\langle k_t \rangle$ is relatively constant—the so-called plateau region—before it undergoes a steep decrease starting around 20% conversion. This gives rise to the “gel effect” of Figure 3, as discussed in Section 2.2.3. Starting around 40–50% conversion, there appears to be a period of relatively gentle decline in $\langle k_t \rangle$. This has been interpreted as being due to so-called reaction-diffusion control of termination:¹²⁷ the translational diffusion of macroradicals is so slow, due to the high concentration of polymer which gives rise to very high viscosity and extensive chain entanglements, that the fastest mode of motion of a radical chain end is that effected by addition to monomer.¹²⁸ In this situation, termination ceases to be chain-length dependent, and the rate coefficient is given by the remarkably simple equation¹²⁷

$$k_t = C_{RD}(1-x)k_p \quad (53)$$

The reaction–diffusion proportionality constant C_{RD} is a function of $c_{M,0}$, σ (52), and a parameter characterizing the random-coil dimensions of the polymer. At very high conversions, $\langle k_t \rangle$ becomes so small (Figure 30) that one would certainly expect (53) to be valid.³⁵

Given the multifaceted and extreme variation of $\langle k_t \rangle$ with x that is displayed by MMA, the complete lack of variation in the DA data of Figure 30 comes as a surprise: the plateau region seems to extend over the entire range of conversion, and there is no hint of reaction diffusion ((53) predicts a fivefold decrease in k_t in going from 0 to 80% conversion). Of course, from a strictly modeling point of view, the extremely simple behavior of DA makes life very easy: one can just take $\langle k_t \rangle(x)$ to be a constant. However, from another point of view, this result makes life difficult: how is it that increasing polymer concentration gives rise to such a spectacular autoacceleration of rate in the case of MMA, but to no change in $\langle k_t \rangle$ for DA? After all, bulk viscosity also increases by many orders of magnitude in going from DA to poly(DA), so why is there no gel effect in this system? This makes the very important point that the variation of k_t with x is not always sensitive to changes in macroviscosity; it is especially important to be aware that this is the case during the initial plateau region, as Figure 30 makes clear.

The two examples of Figure 30 may be considered as extremes: most monomers have $\langle k_t \rangle(x)$ that varies more than DA's but less than bulk MMA's. Given the successes outlined in Section 5.2, one may be optimistic that as CLDT methods—so far largely only applied to dilute solution conditions—are turned to the entire range of conversion, the mysteries of Figure 30 will clear up. Manifestly, the composite model is very successful for the initial plateau region (which can be quite extended, e.g., the DA data of Figure 30); however, it remains to be seen how (51) fares beyond these conditions, when, for example, termination may come under reaction-diffusion control, meaning that the composite model loses relevance as envisaged (although employing $\alpha_S = \alpha_L = 0$ will render it still mathematically correct). Beyond low conversions, one can also anticipate that the MMD of dead polymer will exert an influence on termination rate coefficients, because translational diffusion coefficients are known to depend on the size and architecture (e.g., degree of crosslinking) of the matrix polymer

through which movement occurs. So the formulation of a truly microscopic description of termination, along the lines of that presented in Section 5.2, is still some way from realization for the full range of conversion.

Given this situation, it is appropriate to introduce the model of Buback for variation of k_t with x :¹²⁹

$$k_t = \frac{1}{(k_{tSD})^{-1} + \eta_r/k_{tTD,0}} + \frac{C_{RD}(1-x)}{(k_{pC})^{-1} + \eta_r/k_{pD,0}}$$

where $\eta_r = \exp(C_\eta x)$ (54)

Although this model does not incorporate CLDT explicitly (hence discarding the brackets around k_t), it does so to some extent in that it is based on many of the concepts outlined above. To start with, there is the recognition of segmental diffusion (k_{tSD} ; Figure 28), translational diffusion (k_{tTD} ; Figure 28), and reaction diffusion steps, all contributing to k_t .¹²⁹ There is inclusion of viscosity effects, whereby variation of η_r , which is the viscosity relative to that at zero conversion, results in change of k_{tTD} from its zero-conversion value $k_{tTD,0}$. This also results in variation of k_{pD} , the diffusion-controlled value of k_p . This is important in glassy systems, in which k_p is lower than its chemically controlled value k_{pC} (all k_p values discussed to date have been of the latter nature).

Equation (54) has proven very useful for modeling and for reaching a qualitative understanding of the different $k_t(x)$ variations that are observed from system to system (e.g., Figure 30): these stem from the interplay of termination mechanisms being different.^{66,129} An example of using equation (54) for these purposes is presented in Figure 31. Firstly, the 0 °C MMA data of Figure 30 is fitted with (54). Not only does this give a relatively simple mathematical description of a highly nuanced variation, but it also clearly reveals four mechanistic regions, as originally postulated by Soh and Sunderberg.¹³⁰ These are, and are marked, as follows: (i) the initial plateau region, in which $k_t \approx k_{tSD}$, that is, segmental diffusion is rate determining; (ii) the gel effect starting and taking off due to a switchover to translational diffusion being the rate-determining termination step; (iii) k_{tTD} becoming so low that reaction-diffusion takes over as being rate determining; (iv) still the case that $k_t = k_{tRD}$, but the switchover to diffusion-controlled propagation means that k_t once again decreases strongly

Figure 31 Variation of termination rate coefficient k_t with fractional conversion x of monomer into polymer. Points: bulk polymerization of methyl methacrylate at 0 °C (from Figure 30). Lines: evaluations of (54): unbroken: fit to points, obtained with $k_{tSD} = 1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, $k_{tD,0} = 5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $C_\eta = 27$, $C_{RD} = 80$, $k_{pC} = 142 \text{ M}^{-1} \text{ s}^{-1}$,⁸⁹ and $k_{pD,0} = 5 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$; large dashes: as for fit except $C_{RD} = 20$; small dashes: as for fit except $k_{tD,0} = 1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$; and dots: as for fit except $k_{tSD} = 5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$. The regions marked (i)–(iv) are described in the text.

with x , as in region (ii). Such behavior is evident in the 50 °C MMA data of Figure 30 for $x > 0.8$.

Figure 31 also presents evaluations of (54) with alternative parameter values. As is shown, broadly speaking it is the case that C_{RD} influences regions (iii) and (iv), k_{tSD} region (i), and $k_{tD,0}$ region (ii). This gives an idea of the utility of the equation and how parameter values need to be tweaked in order for different situations to be described. For example, the DA data of Figure 30 obviously indicate that parameter values are such that $k_t = k_{tSD}$ over a tremendously extended range of conversion.

5.4 Termination in Copolymerization

Being diffusion-controlled, termination is different from propagation, which is chemically controlled (except in the uncommon event of a system being glassy). For this reason, termination in copolymerization should be described differently from propagation, because terminal and penultimate unit effects on radical reactivity are concepts tied to the notion of chemical control. It is therefore a surprise that in fact the treatment

of copolymerization termination has proceeded in exactly this direction, with the most recent work finding that the following equation is well suited for describing data:^{126,131,132}

$$(k_t)^{0.5} = p_{11}(k_{t,1111})^{0.5} + p_{21}(k_{t,2121})^{0.5} + p_{12}(k_{t,1212})^{0.5} + p_{22}(k_{t,2222})^{0.5} \quad (55)$$

In this equation, $k_{t,badc}$ is the rate coefficient for termination of chain-end *ba* with chain-end *dc*, while p_{ba} is the fraction of radicals of type R_{ba} (34), and may be calculated via parameters from fitting of F_1 and k_p data.

Equation (55) has recently been critiqued as part of a review covering termination in copolymerization.⁵ The nub of the matter is that, if k_t depends only on the last two units of a copolymer chain, then it seems impossible to explain that termination is chain-length-dependent, that is, it depends on the entire length of a chain. This is not to dispute that simple whole-chain models of termination in copolymerization—as have been reviewed⁴⁹—often function inadequately in describing the variation of copolymerization k_t with f_1 .^{49,116,131} However, it is to suggest that something fundamental is still lacking from our understanding of termination in copolymerization.

In view of this situation, attention is drawn to the following empirical model:¹³³

$$\log k_t = f_1 \log k_{t,1} + f_2 \log k_{t,2} + f_3 \log k_{t,3} \quad (56)$$

As stated here, this equation is for a three-component system, where $k_{t,i}$ refers to homotermination rate coefficient of monomer *i* and f_i to its mole fraction. It is obvious how to adapt (56) for any number of monomers being present. This equation has been found to provide a good description of the plateau-region (i.e., low conversion) data from acrylate terpolymerization,¹³³ methacrylate terpolymerization,¹³³ and acrylate/methacrylate copolymerization.¹²⁶ In the decade since these studies, the relationship between solution viscosity and $k_t^{1,1}$ at low conversion has been established (Section 5.2). This is of interest in that viscosity of a liquid mixture is given by a relationship of the form of (56). This may explain the successes of this equation, which, it should be mentioned, has the considerable virtue of not containing any adjustable parameters (whereas (55)

Figure 32 The competing termination reactions of disproportionation (rate coefficient k_{id}) and combination (rate coefficient k_{ic}) in radical polymerization of methyl methacrylate. The end groups resulting from the popular initiators 2,2'-azoisobutyronitrile (AIBN;¹³⁴ upper example of A) and bis(3,5,5-trimethylhexanoyl) peroxide (BTMHP;⁸ lower) are also shown.

has two, namely, $k_{t,2121}$ and $k_{t,1212}$). Nevertheless, one should be aware that (56) will not always work; for example, quite clearly it does not describe Ma *et al.*'s styrene/diethyl fumarate data.¹³¹

5.5 Disproportionation-to-Combination Ratio

The fraction λ (11) of termination by disproportionation is not inconsequential: in the event of dead-chain formation being predominantly by termination, it causes DP_n to vary by a factor of 2 (Section 2.3.2), it has a major effect on MMD broadness (Section 2.3.3), and it results in the number of initiator-derived end groups on the polymer being as different as 1 or 2, as shown in Figure 32. All of these effects may be important in terms of material properties, while the third may be of significance for polymer modification chemistry. Given this, the situation portrayed in Figure 33 is shocking: despite over 50 years to tackle the issue, there is no agreement on the value of λ for MMA. This state of affairs reflects the historical difficulty of measuring λ , which means that for other monomers the situation is just as vague in this regard.

Fortunately, the emergence of large-molecule MS promises to remedy this calamitous state. Figure 32

Figure 33 Literature values of the fraction λ of termination by disproportionation as a function of temperature for radical polymerization of methyl methacrylate. The values were obtained by different techniques as indicated. λ_{ave} , the average of all these values of λ , is also shown. [Reprinted with permission from Ref. 8. Copyright 2009 American Chemical Society.]

makes clear that, as long as the mass of the initiating radical is different from the mass of monomer (and multiples thereof), disproportionation and combination give rise to polymer molecules of different molar mass. Thus MS can distinguish species formed by each termination mode, as is clear from Figure 34. Since MS signal intensity reflects the

Figure 34 Portion of the ESI-MS spectrum of poly(methyl methacrylate) obtained from polymerization in benzene solution at 85 °C with BTMHP (Figure 32) as initiator. The molar mass of each of the prominent peaks is given. All of these peaks are combination products (“comb”), disproportionation products (“dis”), or internal standard (*), as indicated. The numbers in brackets are the number of methyl methacrylate residues. For example, the signals labeled $I_{\text{comb}}(8)$ are from oligomer made up of eight MMA units and 2,4,4-trimethylpentyl at each end (Figure 32). [Reprinted with permission from Ref. 8. Copyright 2009 American Chemical Society.]

amount of a species, it should be possible to obtain λ (or, equivalently, $k_{\text{td}}/k_{\text{tc}}$) from an analysis of these intensities.

Since disproportionation produces two polymer molecules whereas combination produces only one (Figure 32), it is the case that $k_{\text{td}}/k_{\text{tc}} = (n_{\text{d}}/2)/n_{\text{c}}$, where the n refer to the *overall* numbers of chains from the respective modes of termination. In originally proposing the above method for λ determination and using it with AIBN (Figure 32), Zammit *et al.*¹³⁴ assumed that this relationship holds also with $n_{i,\text{d}}$ and $n_{i,\text{c}}$, the numbers of chains for *individual* chain lengths i (Figure 34). In fact this is not the case. Starting with (22a) and using other results in Section 2.3.1, it is straightforward to show that⁸

$$\frac{\frac{1}{2}n_{i,\text{d}}}{n_{i,\text{c}}} = \frac{\nu}{(i-1)(\frac{1}{\lambda}-1)} = \frac{\nu(k_{\text{td}}/k_{\text{tc}})}{(i-1)} \quad (57)$$

In other words, there is a natural variation of $n_{i,\text{d}}/n_{i,\text{c}}$, as obtained from MS intensities, with both i and kinetic chain length ν (23b). Using (57), MS data from employing bis(3,5,5-trimethylhexanoyl) peroxide (BTMHP) (Figure 32) as initiator was recently shown to *self-consistently* give the value

$\lambda = 0.63$ for MMA at 85 °C.⁸ Probably not coincidentally, this is almost exactly the same as the average of all the literature values in Figure 33, as shown.

Now that a reliable method for the determination of λ seems to have been developed, it can be hoped that it will be applied to a wide variety of systems. Until that has been done, one really only has the results of small-molecule studies on which to go.^{6,17} The rule of thumb from such investigations is that combination ($\lambda = 0$) will predominate for 2° macroradicals (e.g., styrene and acrylate systems), while disproportionation ($\lambda = 1$) can be significant for 3° macroradicals (e.g., methacrylate systems, as is evident from Figure 34). The physical basis for this rule is that the more energetically favorable reaction, namely, combination, will occur unless there is considerable steric hindrance to the two free electrons becoming proximate enough for a C–C bond to form. Considering Figure 32, it should not be surprising that with MMA there is such hindrance. Even so, the value $\lambda = 0.63$ shows that more combination occurs with MMA than is commonly believed. This emphasizes that the presented rule of thumb is just a starting guideline, not an inviolable principle.

6 SMALL-MOLECULE CHAIN TRANSFER

Values of k_{trX} most commonly are determined using (29). An example of a so-called Mayo plot is given in Figure 35, which shows values of $1/DP_n$ from bulk polymerizations of MMA with different concentrations of the chain-transfer agent (CTA) dodecyl mercaptan (DDM; Section 1.2).⁴³ According to (29), the slope of a plot of $1/DP_n$ versus $c_{\text{DDM}}/c_{\text{MMA}}$ is equal to k_{trX}/k_p . These values are presented in Figure 35. It is evident that $k_{\text{trX}} \approx k_p$ for this system at 40–60 °C, which tells that an MMA macroradical has approximately equal reactivity with DDM and MMA. This is typical for conventional CTAs.

To give some idea of the variation that is possible with k_{trX} values, the above value for DDM with MMA may be compared with two extremes: (1) So-called catalytic chain-transfer agents are certain transition-metal complexes, most notably low-spin Co^{II} complexes such as cobaloximes, that are extremely efficient and are not consumed by the

Figure 35 Reciprocal number-average degree of polymerization $1/DP_n$ from low-conversion bulk polymerization of methyl methacrylate (MMA) as a function of concentration c_{DDM} of dodecyl mercaptan at two different temperatures, as indicated. Points: experimental values;⁴³ lines: linear best fits, with slopes as displayed. [The Kinetics of Radical Polymerization in Encyclopedia of Polymer Science and Technology, November 2010 in Encyclopedia of Polymer Science and Technology. Copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.]

transfer process.¹³⁵ For such species with MMA, it has been determined by the Mayo procedure that $k_{\text{trX}}/k_p \approx 10^4$ at 60 °C.¹³⁵ (2) At the other end of the spectrum, it has been found that $k_{\text{trX}}/k_p \approx 10^{-5}$ for chain transfer to monomer in MMA at 60 °C.¹³⁶ Again, this value was determined using (29). So with these examples one sees variation of k_{trX} by nine orders of magnitude for MMA macroradicals undergoing transfer to different small molecules at 60 °C. Of course, in practice these variations are counterbalanced by concentration variations: the high value of c_M in bulk systems negates the small value of k_{trM} to make transfer to monomer a competitive reaction in many circumstances, while chain transfer to catalytic CTA is kept in check by using only ppm quantities.¹³⁵ The message here is one that was implicitly delivered right at the beginning with (9): it is the *frequency* of transfer $k_{\text{trX}}c_X$ that is important.

It is also interesting to compare the activation energies for these transfer processes. For catalytic CTAs, Heuts *et al.* report that there is hardly any temperature dependence of k_{trX}/k_p , with E_A if anything being slightly negative.¹³⁵ For transfer to MMA monomer, $E_A(k_{\text{trX}}/k_p) = 23 \text{ kJ mol}^{-1}$.¹³⁶ Exactly the same value has been found for transfer

to monomer in styrene.¹³⁷ For DDM with MMA, the situation is unclear. The two values of Figure 35 suggest $E_A(k_{\text{trX}}/k_p) \approx 30 \text{ kJ mol}^{-1}$. On the other hand, Hutchinson *et al.* found essentially no variation of k_{trX}/k_p across 20–80 °C for the same system.¹³⁸ Considering all the data at their disposal, Heuts *et al.* concluded that “the activation energy for k_{trX} exceeds the activation energy for k_p by about 10 kJ mol^{-1} .”⁴³ Given the absolute values of k_{trX}/k_p mentioned above, it is not unreasonable that $E_A(k_{\text{trX}}/k_p)$ for the DDM/MMA system should be in between those of the two “extreme” systems.

A highly interesting result from the study of Hutchinson *et al.* is that k_{trX}/k_p is the same for DDM with MMA, ethyl methacrylate, and *n*-butyl methacrylate, but is 20 times higher with styrene. As is commented, this suggests that “a single set of experiments can be done to characterize the chain-transfer ability of an agent with an entire monomer family.”¹³⁸ Again, this is not unreasonable: for each reaction, the reactant is the same (cf. homopropagation, where the small molecule is different in each case), while the only thing that changes about the radical is the length of the pendant alkyl group, which of course is away from the radical site.

It should be evident from (29) and Figure 35 that the experiments to determine k_{trX}/k_p are undemanding and the data analysis is straightforward. It should also be evident that k_{trX}/k_p values are tremendously important, for transfer often determines MMD; indeed, the purpose of using a CTA is usually to afford control of DP_n . It, therefore, is completely perplexing that *systematic* studies into the variation of k_{trX}/k_p are few and far between (as opposed to one-off measurements, which are numerous¹⁰⁴). For example, the premier data on the variation with temperature of styrene transfer-to-monomer rate coefficients are still considered to be those from 1955, when SEC did not exist, and DP_n values were determined by viscometry!¹³⁷ Given this negligent situation, there is not a lot more that can be reported as known about the mechanism of chain transfer to small molecules. This is an area that is crying out for orderly study. There even exists already a theoretical framework for investigation, in the form of predictions of trends on the basis of TS theory.¹³⁹ It simply remains to start testing and refining these ideas.

7 OTHER INFLUENTIAL REACTIONS

A principal contention of this work is that, if one properly understands the foundations of RP kinetics (Section 2) that follow from the fundamental suite of reactions of Section 1.2, then enormous progress can be made in explaining RP kinetic phenomena. A good example of this is the variation of k_p of hydrogen-bonded monomers with water content (Section 4.2 and Figure 20). This results in large changes in rate, which previously were explained in terms of complexation phenomena and/or the occurrence of additional reactions. However, with the advent of PLP SEC, it has become clear that these variations in rate are largely driven simply by a solvent effect on k_p rather than by any exotic phenomenon.⁹⁵ This notwithstanding, there are situations where the diversity of RP kinetics is due to extra reactions being important. This section presents the two leading examples of such reactions.

7.1 Chain Transfer to Polymer

Chain transfer to polymer (CTP) is the reaction whereby a radical abstracts the hydrogen from a C–H bond on a polymer molecule, thereby transferring the radical activity to the carbon from whence the hydrogen came:

This has long been known to be the signature reaction of ethylene systems, resulting in the short-chain branches (SCBs) and long-chain branches (LCBs) that give LDPE its defining characteristics. In the case of ethylene, CTP involves conversion of a primary radical into a lower-energy secondary radical, as shown above. However, the activation energy for breaking a C–H bond to form a secondary radical is relatively high, meaning that the high-pressure and high-temperature conditions of LDPE synthesis are required to achieve significant rates of CTP. In acrylates, on the other hand, the CTP reaction involves conversion of a secondary radical into a tertiary radical (see below). So there is still an energetic driving force. However, it is

easier to break a C–H bond to form a tertiary radical than it is to form a secondary radical. Thus CTP should occur under milder conditions with acrylates, even though in principle it is the same reaction as with ethylene. Indeed, it has emerged over the last decade¹⁴⁰ that CTP takes place with acrylates at *ordinary* temperatures and pressures, and that it is responsible for many unusual kinetic phenomena in these systems.

This development started with the use of ¹³C NMR to show that the polymer from RP of BA contains quaternary carbons to such a level that approximately 1% of BA units are branch points.¹⁴¹ A few years later, it was established that the predominant form of CTP in these systems is *intramolecular* (leading to SCBs) rather than *intermolecular* (which results in LCBs).¹⁴² In other words, there is a 1,5-hydrogen shift reaction:

This reaction is commonly known as backbiting (rate coefficient k_{bb}). It occurs because the C–H bond is rendered labile by the nearby carbonyl bond, because the TS—a six-membered ring, as intimated above—is energetically favorable, and because the same also holds for the product, a tertiary radical, as already mentioned. These factors are not specific to BA, and so backbiting may be expected to occur with all acrylates.

The above reaction influences RP kinetics because the product radical, which is tertiary in nature, adds to monomer at least two orders of magnitude slower than the reactant radical, which is secondary in nature.^{140,143} Thus the situation is similar to degradative chain transfer (Section 1.2) in that the transfer process yields a relatively stable radical that therefore *retards* the polymerization. That this population of “mid-chain radicals” (MCRs) is significant has been definitively established by quantitative EPR spectroscopy.^{144,145} This work shows that for acrylate homopolymerization at room temperature and above, one must distinguish the two populations of radicals. A *steady-state*

analysis leads to¹⁴⁶

$$k_p = \frac{k_{p\text{SPR}}}{1 + \frac{k_{bb}}{k_{p\text{MCR}}c_M}} \quad (58)$$

Here, SPR stands for secondary propagating radical, that is, the reactant radical in the reaction immediately above. Amongst other things, (58) reveals that, as c_M decreases, overall k_p decreases. The physical reason for this is that slowly propagating MCRs are longer-lived because of the lower monomer concentration. A consequence of this is that overall k_p varies with solvent level in such a way that polymerization rate has order with respect to monomer that is unusually higher than 1 (cf. (16a)), with values of 1.6–1.8 being typical.^{5,140,147} In other words, the additional component is due to k_p varying with c_M . A comprehensive kinetic treatment of the effect of backbiting on steady-state rate has been given and can be recommended.¹⁴⁷

Backbiting also serves to explain unusual PLP-SEC behavior of acrylates. One of the “consistency checks” of this method is that k_p should be independent of the laser pulse repetition rate under normal circumstances.⁶⁵ As is shown in the typical results of Figure 36,¹⁴⁸ acrylates are abnormal. For many years this situation was not understood, and so it was not clear what (if any) k_p value should be recommended for wider use from such results.

Figure 36 Variation of propagation rate coefficient k_p with laser pulse repetition rate t_d^{-1} (where t_d is the time between pulses) from multiple-pulse PLP of 1.35 M acrylic acid in water at 6 °C. Points: experiment;¹⁴⁸ horizontal lines: limiting values of k_p at high t_d^{-1} (upper) and low t_d^{-1} (lower).

Now this situation has been resolved, as follows.¹⁴⁶ The data display a transition from a high value of k_p at high pulse frequency (i.e., small t_d) to a lower value of k_p at low pulse frequency (i.e., long t_d). The high value may be identified as $k_{p\text{SPR}}$: there is so little time between pulses, which produce SPRs, that the entire radical population will be of this nature. When t_d is long, on the other hand, a steady state between SPR creation (by MCR propagation) and loss (by backbiting) will be established and will prevail for most of the time. This means that k_p is given by (58), and so one may easily determine $k_{bb}/k_{p\text{MCR}}$ from the lower limiting value of k_p . For example, the data of Figure 36 deliver $k_{bb}/k_{p\text{MCR}} = 2.4 \text{ M}$.¹⁴⁸ It has subsequently been shown that, as would be intuitively expected, one may in fact obtain k_{bb} and $k_{p\text{MCR}}$ individually from the entire variation of k_p with t_d .¹⁴⁹ Thus so-called frequency-tuned PLP SEC should be regarded as an important tool in the elucidation of acrylate kinetics.

1,5-H-shift reactions can also occur with primary (initiating) radicals, and therefore can be important in explaining initiation kinetics.¹⁵⁰ In general, CTP has a tendency to occur where there is a methyl, methylene, or methine group α to a carbonyl group, for example, vinyl acetate (although this is not definitively established), itaconates, and acrylates, respectively (note the absence of such a group in methacrylate systems). In each case, the adjacent carbonyl bond activates a C–H bond for radical attack. This is an important motif in RP chemistry, as is the 1,5-H-shift reaction, with the two sometimes coinciding, as above for acrylates. Another important motif is β -scission, as now discussed.

7.2 β -Scission

It has already been seen in Section 3 that β -scission is an important reaction in initiation. It is also the basis of RAFT polymerization (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).¹⁵¹ *Depropagation*, the reverse reaction of propagation, is another example of β -scission in RP, becoming important at high temperatures and giving rise to the phenomenon of “ceiling temperature”: the temperature above which

it is not possible to form high polymer. This section will outline how awareness has recently grown of the importance of β -scission in acrylate systems.

Just over a decade ago, it was shown by ^1H NMR that high-temperature polymerization of various acrylates produces macromonomers in high yield.¹⁵² The reaction at work is

As shown, this is a β -scission reaction, and it relies on the prior occurrence of CTP in order to generate an MCR. Because this reaction converts an MCR back into a SPR (as shown), it reduces the retardative effect of backbiting. As this statement makes clear, β -scission competes with propagation as a pathway for MCRs to take.

Barner-Kowollik *et al.* have been intensively studying β -scission in acrylates. They have pointed out that this reaction actually gives rise to a complicated scheme,¹⁵³ because of the reversible nature of β -scission, the fact that β -scission can occur on either side of the radical position in the MCR (i.e., also to the right rather than to the left of the radical above), and the fact that the macromonomer product may have either a chain-starting species (e.g., from initiator) or H as terminus at the saturated end. Nevertheless, the end result can be remarkably simple. Namely, there is the equivalent of the limit of dominant dead-chain formation by transfer to small molecule: in its lifetime a radical undergoes many cycles of (acrylate SPR) addition, CTP, and β -scission, each time producing an H-ended macromonomer. Thus this species is the dominant product, which is why Junkers *et al.* described this chemistry as that of a “macromonomer production machine”.¹⁵³ Therefore it has been used to build up a “macromonomer library”¹⁵⁴ for acrylates, with structures all the time being verified by MS.^{153,154}

8 CONCLUSION

The classical (chain-length-independent) and terminal-model kinetics of Section 2 predate 1985, but otherwise almost all the work presented in this

article has taken place in the last 25 years. One may therefore be astounded at the progress that has been made in RP kinetics over this period: from a position of understanding almost nothing, now a vast amount is understood. The irony is that many outsiders, and even quite a few insiders, have little appreciation that these exciting and important developments have been occurring. As has been demonstrated here, the key to all this progress has been the development of the proper *machinery*. By this word is meant both robust, inquisitory experimental methods such as MP PLP and SP PLP EPR, and practicable kinetic equations for the treatment of subtle but influential phenomena such as chain-length-dependent termination, penultimate-unit effects in copolymerization, and backbiting. The wielders of these tools can expect to keep the progress rolling on as they tackle the many fundamental issues in RP kinetics that remain to be addressed.

Radical Polymerization in Industry

Peter Nesvadba

Performance Chemical Research, BASF Schweiz AG, Basel, Switzerland

1 INTRODUCTION

The goal of this article is to provide a brief overview of radical polymerization (RP) in industry. It will highlight the role of this technique in the context of polymer industry and review its mechanistic and process aspects from the point of view of industrial polymerization. Then, recent progress in industrial applications of controlled RP will be shown. Of course, treatment of such a multifaceted discipline as industrial RP (IRP) is possible only in very limited depth. Therefore, only the most salient features of IRP will be discussed and references for further reading will be given. In accord with the IUPAC recommendation,¹ the term *radical polymerization* will be used instead of *free radical polymerization*.

Life as we know it would not be possible without synthetic polymers, which are commonly called *plastics*. The term *plastics* should not be confused with the technical adjective *plastic*, describing permanent deformation of materials that were strained beyond a certain point. Thus, plastics in this article incorporate all synthetic polymers and macromolecular materials, not only those undergoing plastic (thermoplasts) or elastic (elastomers) deformation but also highly cross-linked and hard thermosetting polymers. Diverse semisynthetic macromolecular materials such as vulcanized rubber, celluloid, or galalith were discovered and already used in the nineteenth century. However, the spread of polymers to every aspect of modern life was possible only after the fundamentals of polymer science

were laid down during 1920–1930.^{2,3} An account of the history of polymers has been given by Morawetz.⁴

The industrial production of several plastics such as bakelite, polystyrene (PS), low density polyethylene (LDPE), or poly(vinyl chloride) (PVC) already started before World War II. However, only the progress in science and technology and the economic growth of the postwar period allowed the worldwide production of polymers to grow at around 9% per year, from 1.5 million tons (mt) in 1950 to about 230 mt in 2009. Of these 230 mt, 55 mt was produced in Europe⁵ (Figure 1). In terms of volume (m³), the production of polymers exceeds that of iron and steel.

Globally, the long-term growth of plastics is expected to be at around 4% and hence higher than the gross domestic product (GDP) growth. The average worldwide consumption⁵ of plastics is significantly below that of the industrialized regions (Figure 2), thus leaving room for future growth.

Up to 2015 and beyond, the fastest growth is expected in Asia. One of the important stimulators of the future demand for polymers is the growing concern about climate change. In fact, more than 14% of all greenhouse gases worldwide are generated by the transportation sector. Reducing the weight of cars through the replacement of metals by plastic can cut a vehicle's weight by up to 30%, resulting in a significant reduction in fuel consumption. The proportion of plastics in a typical Western European car is about 15% today (160 kg), compared with 6% in 1970. By 2020,

Figure 1 Worldwide production of polymers 1950–2009.

Figure 2 World production of polymers 2009, regional split.

plastics could account for more than 25% of a car's weight.⁶

Countless polymers are known in the literature, but the number industrially manufactured polymers is relatively small. For example in 2009, nine types of polymers accounted for 77% (176 mt)⁶ of the 230 mt⁵ of polymers produced worldwide (Figure 3). The five most important plastics are thermoplastic polymers, namely polypropylene (PP), high density polyethylene (HDPE), linear low density polyethylene (LLDPE), LDPE, and PVC, of which 143 mt were produced.

The rest are smaller volume polymers such as polyesters, with poly(ethylene terephthalate) (PET) as the most important example, PS as well

as engineering plastics, and high-performance polymers. The latter exhibit superior mechanical and thermal properties under a wide range of conditions. As their name suggests, these are used in the manufacture of parts or in applications requiring extraordinary performance rather than for construction, containers, or packaging, which is the domain of commodity polymers. Some examples of engineering plastics and high-performance polymers are acrylonitrile–butadiene–styrene (ABS) copolymers, polycarbonates (PCs), polyamides (PAs), polyurethanes (PURs), polysulfones (PSUs), polyetherketones (PEKs), polyetheretherketone (PEEKs), polyoxymethylene (POM), polyimides (PIs), polyphenylenesulfide (PPS), polyphenylene

Figure 3 World's largest volume polymers.

oxide (PPO), or fluoropolymers (e.g., Teflon, polytetrafluoroethylene (PTFE), to name just the most relevant. Additionally, there is the important group of thermosetting polymers^{7–9} including epoxides, phenol-formaldehyde, urea, and melamine polymers, as well alkyds and unsaturated polyester resins. Last but not least, must be mentioned the silicone-based¹⁰ polymers. A special case is the family of dispersion^{11,12} polymers that have in common the same state of aggregation but are diverse from the point of view of their chemical composition. Latest data on production volumes of individual polymers and their regional split have been published.¹³

The classes of polymers differ significantly not only in their production volume but also in their selling price,^{14,15} which is 0.5–2.5€ kg^{−1} for commodity polymers, 10–12€ kg^{−1} for PTFE or PSU, and about 60€ kg^{−1} for PEEK. Prices of high-tech polymeric specialties, for example, those for the electronic industry, are even much higher. As the same polymer is often commercialized by different companies under different names, a plurality of trade names¹⁶ exists.

A number of good monographs^{17–21} and reference works^{22–24} provide detailed information on industrial polymers and their applications. Domininghaus *et al.*¹⁴ provides a compilation of physical and technical data that are important for a professional selection of an optimal polymeric material for a given application.

Synthetic polymers are prepared from low molecular weight building blocks called *monomers*

Figure 4 Mechanistic classification of polymerization processes.

by a process known as *polymerization*. Existing macromolecules can be further modified by polymer analogous reactions. Polymerizations can be divided from a mechanistic point of view² into several classes. RP belongs to the class of chain-growth polymerizations (Figure 4).

Polymers produced by RP represent roughly 40–45% of all industrial polymers, which ranks this method among the most important industrial polymerization techniques. Polymers prepared by nonradical processes are not discussed in this article. Abundant literature is available on ionic,^{25–29} step-growth,^{9,29–31} coordination,^{29,32–36} and group-transfer polymerization³⁷ methods.

Nevertheless, it should be noted that there are other industrially important polymer technologies and applications that are based on radical processes. Thus, millions of tons of unsaturated polyester resins^{9,31,38} are cured (cross-linked) with radical initiators, predominantly peroxides. The drying of alkyd resins^{39,40} also proceeds via the radical mechanism. Photopolymerization of coatings, printing inks, adhesives, and micro-electronic components is a multibillion dollar business and still rapidly growing. Radically induced cross-linking^{41,42} of polymers, controlled degradation^{43–45} of the molecular weight of polypropylene, and modification of polyolefins by grafting^{41,46–48} of polar monomers are other examples. Finally, radicals are very often involved in the thermally and photochemically induced degradation^{49,50} of polymers (e.g., in autoxidation) as well as in the mode of action of the necessary stabilizers^{51,52} used to prevent or retard this deterioration.

2 GENERAL AND MECHANISTIC ASPECTS OF INDUSTRIAL RADICAL POLYMERIZATION

The dominant position of RP in industry originates from several unique characteristics that differentiate it from other polymerization methods. Thus, in contrast to ionic or coordination polymerization, RP is tolerant of protic solvents and trace impurities such as oxygen or monomer stabilizers. Consequently, it can be conducted in polar solvents such as alcohols or, more importantly, water with monomers that are not rigorously dried or purified. Furthermore, a large number of low-priced monomers are available. Thus, from an economical point of view, RP is the technique of choice. For example, the cost to polymerize styrene by anionic polymerization is about 50% higher⁵³ than for RP.

2.1 Monomers

Many molecules containing unsaturated homo or heteronuclear double bonds, dienes, trienes, strained cycloaliphatics, *exo*-methylene-substituted cyclic compounds, or vinylcyclopropanes are amenable^{2,54} to RP. However, the major industrial monomers are compounds **1** (Scheme 1) containing C=C double bond(s) where X is primarily X=H, (CH₃) and Y=H, Cl, COOH, COOR, CONH₂, CN, OCOCH₃, C₆H₅, -CH=CH₂), which serve as precursors of the corresponding polymers **2**. Besides the basic monomers that are produced on a very large scale, there exists a variety of specialty monomers that are used to make homopolymers or copolymers with specific properties. Examples are the styrene derivatives 1,4-divinylbenzene, *p*-vinylbenzyl chloride, and *p*-acetoxystyrene, 4-vinyl pyridine, *N*-vinyl pyrrolidone, various esters and amides of acrylic and methacrylic acid (e.g.,

n-butyl acrylate, 2-hydroxyethyl (meth)acrylate, 2-dimethylaminoethyl (meth)acrylate, glycidyl methacrylate, *N*-isopropyl acrylamide), and a variety of (meth)acrylates of polyhydric alcohols (e.g., ethylene glycol, trimethylolpropane, or pentaerythritol). The latter, by virtue of their high functionality, are used as cross-linkers. The synthesis, properties, and applications of specialty monomers are summarized in the book⁵⁵ by Havelka and McCormick. A compilation of commercially available specialty monomers for formulations cured by photopolymerization is provided by Webster *et al.*⁵⁶

The most important monomers along with the applicable polymerization processes and typical uses of the polymers are shown in Table 1.

Technological and economic information on the industrial synthesis of monomers can be found in the monograph of Arpe.⁵⁷ The current raw material base for monomers consists almost exclusively of crude oil and natural gas and will remain so also in the near future. It should be mentioned⁵⁸ that only ~4–8% of crude oil is used for polymer production, the rest serving predominantly as a source of energy. However, in view of the limited availability and increasing price of oil and gas, a shift⁵⁹ to monomers and polymers from renewable⁶⁰ resources, a renaissance of coal, as well as increasing importance of chemical recycling⁵⁸ of polymeric materials is foreseeable.

2.2 Mechanism of Radical Polymerization

The mechanism of RP is now well understood even though some problems such as control of the stereochemistry of the propagation step or sequence control⁶¹ are still not solved. On the other hand, powerful techniques of controlled RP have been developed in the last 20 years and the first commercial applications are appearing. A comprehensive treatment of the chemical and

Scheme 2 Key mechanistic steps of radical polymerization.

mechanistic aspects of RP is provided by the outstanding monographs⁵⁴ of Moad and Solomon, Matyjaszewski and Davis⁶², and others^{63,64} (see also **Kinetics of Polymerizations**). The mechanism of RP consists of several steps as depicted in Scheme 2.

The numerical values for important parameters of RP are given in Table 2.

As the detailed discussion of this generally accepted mechanism is available elsewhere, only those points of industrial importance will be briefly highlighted.

Table 2 General range of values for key parameters of radical polymerization.

$k_d = 10^{-4} - 10^{-6} \text{ s}^{-1}$	$k_i \approx k_p = 10^2 - 10^4 \text{ M}^{-1} \text{ s}^{-1}$	$k_{tc} \approx k_{td} = 10^6 - 10^8 \text{ M}^{-1} \text{ s}^{-1}$

**Scheme 3** Mayo mechanism of styrene thermal autopolymerization.

2.3 Initiators and Initiation

Initiation of RP begins with the generation of primary radicals (Scheme 2) from the initiator or initiating system. Addition of the primary radicals to the monomer then affords the initiating radicals. The dissociation of the initiator is generally much slower ($k_d \sim 10^{-5} \text{ s}^{-1}$) than the addition of primary radicals to monomer molecules ($k_i \approx 10^4 \text{ M}^{-1} \text{ s}^{-1}$). A comprehensive discussion of all aspects of the different classes of initiators or initiating systems and the various kind of primary radicals (C, O, S, Si, or P-centered) is provided in the monograph⁵⁴ of Moad and Solomon. A survey of radical initiators including decomposition kinetics and half-life times can be found in the handbook⁶⁶ of Denisov and coworkers and to a smaller extent in the *Polymer Handbook*.⁶⁷ Similar information on commercially available initiators is accessible on the websites of the major producers such as AkzoNobel, Arkema, and Wako Chemicals. Braun recounts the origins and development of RP from a historical point of view.⁶⁸ The most important initiators and initiating techniques for industry are discussed briefly below (see also **Overview of Radical Initiation**).

2.3.1 Thermal Autoinitiation

Styrene and its derivatives are the most prominent examples of monomers that generate initiating radicals by a purely thermal reaction without participation of other reagents. For example, at 180 °C, 80% conversion of pure styrene monomer to polymer occurs in 40 minutes. The most accepted mechanism⁶⁹ of styrene autoinitiation involving formation of a Diels–Alder adduct **3** (Scheme 3)

was proposed by Mayo. Thermal self-initiation of styrene is used industrially to prepare extremely pure PS devoid of any initiator and derived functional groups. Thermal autoinitiation of other monomers (acrylates or methacrylates⁷⁰) is much slower and without any practical importance.

2.3.2 Azoinitiators

Industrially important azoinitiators are symmetrical dialkyldiazenes **4** (Scheme 4) bearing tertiary R groups with substituents (X) which serve to stabilize the incipient radical, thus lowering the decomposition temperature. The most important member of this class is azo-isobutyronitrile **5** (AIBN).

The thermal decomposition of azoinitiators generates two C-centered radicals and nitrogen. The mechanism of the thermal and photochemical decomposition of dialkyldiazenes has been reviewed by Engel.⁷¹ Unfortunately, the yield of initiating radicals is practically never quantitative. In fact, depending on the viscosity of the surrounding media and size of the primary radicals, the latter can undergo an irreversible cage termination reaction leading to inactive products. Hence, only those primary radicals that escape from the solvent/monomer cage participate in chain initiation. This cage effect negatively influences the initiator efficiency (f) which is defined by (1) for an initiator generating n (usually 2) primary radicals and typically⁷² lies in the range of 0.5–0.7 (or 50–70%).

$$f = \frac{\text{Rate of initiation}}{n \times \text{Rate of initiator decay}} \quad (1)$$

The cage termination products may be problematic. For example, the dinitrile **6** formed from AIBN

Scheme 4 Azoinitiators and their decomposition mechanism.

is a highly toxic compound,^{73,74} which prevents the use of AIBN for making polymers that would come into contact with foodstuff. The C–N dimer **7** can redissociate⁷⁵ into the radicals **8**, thus complicating the polymerization kinetics. Furthermore, the methacrylonitrile **9** is readily copolymerized with the monomer and can influence⁷⁶ the polymer properties.

The thermal decomposition of azoinitiators follows first-order kinetics (2), and the temperature dependence of k_d obeys Arrhenius law (3). A very important characteristic of a polymerization initiator is its half-life ($t_{1/2}$) (4), which is the time required to reduce the original initiator concentration by 50%. It can be easily calculated using (2–4) and the tabulated Arrhenius parameters A and E_a .

$$-\frac{d[I]}{dt} = k_d[I] \quad (2)$$

$$k_d = Ae^{-\frac{E_a}{RT}} \quad (3)$$

$$t_{1/2} = \ln \frac{2}{k_d} = \frac{0.693}{k_d} \quad (4)$$

where k_d is the rate constant of initiator decomposition (s^{-1}); $[I]$ is the initiator concentration (M); A is the Arrhenius frequency factor (s^{-1}); E_a is the activation energy for the initiator decomposition (J mol^{-1}); R is $8.3142 \text{ J mol}^{-1} \text{ K}^{-1}$; T is the temperature in K; and $t_{1/2}$ is the half-life time (s^{-1}).

Activation energies of thermal homolysis of azoinitiators lie in the range of $100\text{--}170 \text{ kJ mol}^{-1}$ and thus decomposition rates are very sensitive to temperature. For example, $t_{1/2}$ of AIBN decreases from 10 hours at 65°C to 20 minutes at 90°C and to ~ 45 seconds at 110°C . In terms of volume, AIBN is the most important azoinitiator. There are several other initiators on the market with different cleavage temperatures, solubility in water or organic solvents, or functional groups (X) other than CN. The latter allow introduction of the functionality into the polymeric chain. Examples⁷⁷ are compounds **10–14** shown in Scheme 5.

In general, advantage of azoinitiators over the widely used peroxides is their lower tendency to undergo chain transfer reactions. This leads to better defined polymers containing fewer oxygenated impurities, which enhances their thermal or photochemical stability.

2.3.3 Peroxides

Peroxides $\text{R}^1\text{--O--O--R}^2$ are the most important industrial radical initiators, exceeding the production volume of azoinitiators by orders of magnitude. About 45% of the 207 000 tons of peroxides that were utilized⁷⁸ in 2007 by the worldwide plastics industry was used to initiate RPs. The rest found application in radically induced cross-linking

Scheme 5 Examples of commercial azoinitiators with indicated temperatures ($^{\circ}\text{C}$) for a half-life of 10 hours.

Scheme 6 Examples of commercial peroxide initiators with indicated temperatures ($^{\circ}\text{C}$) for a half-life of 10 hours.

of unsaturated polyester resins and polyethylene, in controlled reduction of molecular weight of polypropylene, and as synergists for flame retardants. A detailed analysis of the markets, applications, and future trends for organic peroxides can be found in the market study⁷⁸ of Townsend Polymer Services. The most important commercial peroxide initiators are dialkylperoxides, diacylperoxides, hydroperoxides, peroxyesters, peroxydicarbonates, peroxyketals, ketone peroxides, and inorganic peroxides. Several dozens of derivatives with varying half-life, solubility, and volatility are available on the market. Typical examples are the compounds **15–22** shown in Scheme 6.

The chemistry of peroxides was recently reviewed.⁷⁹ Generation of radicals from peroxides occurs via homolysis of the weak $-\text{O}-\text{O}-$ bond. The bond dissociation energies^{66,80} of most peroxides lie between 127 (dibenzoyl peroxide) and 211 kJ

mol^{-1} (H_2O_2). The nature of the primary radicals depends⁵⁴ on the structure of the starting peroxide and the type of cage reactions. For example, thermolysis of dibenzoylperoxide **16** gives rise to the relatively long-lived benzoyloxy radicals **23**. As **23** can also decarboxylate to give phenyl radicals **24**, both these radicals are involved in chain initiation. The competitive irreversible coupling of **23** and **24** yields the cage products **25** and **26** (Scheme 7).

Analogously, hydroperoxides generate alkoxy and hydroxyl radicals, and dialkylperoxides are sources of alkoxy radicals. Aliphatic diacylperoxides yield predominantly alkyl radicals because of the very fast in-cage decarboxylation of primary aliphatic acyloxy radicals. However, the simple homolysis of the $-\text{O}-\text{O}-$ bond of peroxides is not the sole decomposition mechanism. In fact, the radical chemistry of peroxides is more complex than that of azoinitiators. Diacyl peroxides are susceptible

Scheme 7 Thermal decomposition of dibenzoyl peroxide.

Scheme 8 Induced decomposition of dibenzoyl peroxide with (a) radicals and (b) aromatic amines.

to radical-induced decomposition resulting from homolytic attack of a radical on one of the oxygens of the $-O-O-$ bond (Scheme 8). The consequence is chain transfer from the growing chain to the initiator with the concomitant incorporation of a benzoyloxy group into the polymer in a form of a *secondary* ester. Such end groups may negatively influence the thermal (PS⁷⁶) or hydrolytic (PVC⁸¹) stability of the polymer. Of practical importance is the decomposition of dibenzoyl peroxide **16** induced⁸² by aromatic amines (Scheme 8). As this reaction takes place already at room temperature or even below, addition of an amine synergist (often called *accelerator*) to a polymerizable composition containing **16** allows the polymerization to occur at room temperature or even around 0 °C. Two-component initiating systems consisting of **16** and *N,N*-dimethylaniline **27** (or similar derivatives) are widely used for

Scheme 9 Radical generation from a persulfate.

the room-temperature curing^{9,31,83} of unsaturated polyesters.

The water soluble sodium, potassium or ammonium salts of peroxydisulfuric acid (persulfates) are important initiators for aqueous and emulsion (EP) polymerizations. The mechanism of radical generation from the persulfate dianion **22** depends on pH. Homolytic cleavage affording the sulfate radical anion **28** dominates in neutral media (Scheme 9) whereas heterolytic cleavage occurs in acidic solution.

Scheme 10 Redox reaction between (a) persulfate and hydrogen sulfite, (b) hydroperoxide and Co ions.

Furthermore, redox reactions occur between persulfates **22** and reducing agents such as 2-mercaptoethanol, thiourea, sulfites,⁸⁴ amines, dithionites, or thiosulfates. Such initiating systems are frequently employed in aqueous EPs. In addition to the amine–dibenzoylperoxide system, the redox reaction of hydroperoxides with ions of various transition metals (mostly Co or Mn) is commonly used for the room-temperature curing of unsaturated polyesters. Typically, two-component initiating systems consisting of a hydroperoxide (e.g., cumyl hydroperoxide or ethylmethylketone peroxide **21**) and a Co- or Mn-based accelerator (e.g., cobalt octoate or manganese naphthenate) are used for this purpose (Scheme 10).

Redox-initiated polymerizations were reviewed⁸⁵ by Misra and Bajpai. A comprehensive discussion of the initiating mechanism of the different peroxide families is available in the monograph⁵⁴ of Moad and Solomon.

Organic peroxides, as well as azoinitiators, are unstable compounds and decompose exothermally at relatively low temperatures. They must be handled

and stored properly and most require some form of temperature control. Guidelines for the safe handling of these initiators were recently reviewed⁸⁶ and are available on the web pages⁸⁷ of their manufacturers.

2.3.4 Miscellaneous Radical Initiators

Peroxides are the most important industrial initiators for RP followed by azoinitiators. Much smaller volumes of specialty initiators are also used. One example is 2,3-dimethyl-2,3-diphenyl butane, known as Perkadox[®] 30 (AkzoNobel), used in styrene polymerization. This C–C dimer thermally dissociates into cumyl radicals ($t_{1/2} = 1$ hour at 259 °C in PhCl). Novel initiators⁸⁸ with improved handling and storage stability as compared to peroxides or azo-compounds are highly desirable and are slowly appearing on the market. Examples are sterically hindered *N*-acyloxyamines⁸⁹ **29** and silylated benzopinacol⁹⁰ derivatives **32** (Scheme 11). The proposed mechanism of action of the *N*-acyloxyamine radical initiators **29** involves⁹¹

Scheme 11 *N*-Acyloxyamine and silylated benzopinacol initiators.

homolysis of the N–OC bond to generate *N*-aminyl radicals **30** and acyloxy radicals **31**. This contrasts with the NO–C bond homolysis of alkoxyamine initiators for controlled RP.

Initiators for controlled RP are discussed in respective sections.

2.3.5 Photoinitiators

Photoinitiators^{92–95} are compounds that generate primary radicals upon irradiation with light of a suitable wavelength (generally UV).

They are niche products used to initiate polymerization (curing) of radically polymerizable/cross-linkable coatings (e.g., on furniture, flooring, metal, plastics, automotive parts, paper, optical fibers), printing inks, and adhesives, or in the production of microelectronic devices. They are not used, however, in the production of bulk, large-volume polymers. Radiation curing in a broader sense⁹⁶ also encompasses curing initiated by electron beam⁹⁷ (EB) or cationic⁹² photoinitiators, but these topics are not treated here.

A UV-curable formulation⁹⁷ for a coating, ink, or adhesive consists of a mixture of (i) 30–50% specialty monomers or oligomers,⁵⁶ which impart most of the basic properties to the final cured or cross-linked material; (ii) 10–40% reactive diluents or monomers, which permit the adjustment of formulation viscosity and crosslink the oligomer; (iii) 1–20% additives and pigments; and (iv) 0.5–8% photoinitiators which provide the initiating radicals. Functionally terminated low to medium molecular weight polymerizable oligomers are the backbone of UV-curable coatings and determine properties of the cured coating: for example, hardness, chemical resistance, and flexibility. Commonly used oligomers include acrylates of polyhydric alcohols, oligomeric diols, and polyols having epoxy-, urethane-, polyester-, or siloxane backbones. Of less importance are the unsaturated polyesters or thiol–ene systems. Oligomers based on methacrylates are sometimes used in combination with acrylates in order to improve thermal resistance and mechanical hardness of the finished coating.

UV-light-triggered radiation curing provides several advantages over thermal curing, which include (i) very rapid cure occurring within seconds,

(ii) ambient temperature curing which permits the coating of heat-sensitive substrates such as wood and plastics, (iii) more efficient, compact operations, (iv) zero or low solvent levels, and (v) good film properties and performance. Among the drawbacks of UV curing is the high sensitivity toward oxygen inhibition, the impossibility to cure thick pigmented layers, and the difficulty to cure three-dimensional objects (shadow zones). Details on equipment for UV and EB curing (lamps, electron guns, machinery) can be found in the monograph⁹⁸ of Mehmert and coworkers. A comprehensive overview of photopolymerization in polymer science and technology is provided in the four-volume compendium^{99–102} of Fouassier and Rabek, and Marrion reviews¹⁰³ the chemistry and physics of coatings.

The market study by SRI Consulting¹⁰⁴ provides a detailed analysis of the global market for radiation-curable products. In 2007, the market volume was estimated at 390 000 metric tons with an average growth of 4–5% per year.

Radical photoinitiators^{92–95} are generally divided into two classes. Compounds undergoing homolytic bond cleavage (Norrish I cleavage) upon irradiation are termed *type I photoinitiators*. Typical examples are α -hydroxyketones **33–34**, α -aminoketones **35**, benzil dialkylketals **36**, acylphosphine oxides **37**, and bisacylphosphine oxides **38** (see Scheme 12). The oxime esters (e.g., **39**) photoinitiators^{95,105,106} were developed for highly specialized applications in electronics such as photocuring of color filter resists and the black matrix resin of liquid crystal displays.

Type II photoinitiators, on the other hand, interact in their excited state with a second molecule (coinitiator) to generate radicals in a bimolecular reaction (Scheme 13). Derivatives of benzophenone **40** and thioxanthone, for example **41**, are the most important type II photoinitiators. Amines such as *N*-methyldiethanolamine, triethanolamine **42**, and esters of 4-dimethylamino benzoic acid are typical examples of coinitiators. The resin matrix itself can also act as a coinitorator if it possesses easily extractable hydrogen atoms. Alkyl phenylglyoxylates **43** are also considered¹⁰⁷ as type II photoinitiators. A compilation of commercially available photoinitiators and a discussion of their chemistry and applications is provided in the book by Dietliker.⁹³

One of the biggest challenges⁹⁵ for the future growth of the UV market is the development of

Scheme 12 (a) Type I photoinitiators and (b) some of their representative examples.

Scheme 13 Type II photoinitiators.

nonextractable, odorless, and low-migration photoinitiators. Such products will be applicable in coatings destined for indirect food contact. So far, few UV-curable systems are present in this market because the photoinitiator or its fragments can migrate into foodstuffs.

2.4 Propagation

Propagation is the repeated addition of the growing macroradical to monomer. The rate constants of propagation are typically in the range of $k_p \sim 10^2\text{--}10^4 \text{ M}^{-1} \text{ s}^{-1}$. The magnitude of k_p

depends slightly on the degree of polymerization X_n of the macroradical, at least for the first (~ 10) propagations steps. The mechanistic aspects of the propagation step of RP are well understood^{54,62,63} and need not to be discussed here. However, one should note that the simplified picture of a 100% regiospecific head-to-tail addition (Scheme 1) which is shown in many introductory texts on polymerization is not completely correct. In fact, head-to-head addition is observed in polymerizations of most monomers. For example, it occurs to the extent of 11% in the polymerization of allyl esters¹⁰⁸ (Scheme 14).

Scheme 14 Regiosequence isomerism—head versus tail addition.

Scheme 15 Ring-opening polymerization of a cyclic monomer.

Of course, even more variations are observed with diene (1,3-butadiene, isoprene, chloroprene) monomers. It should be noted in this context that even the addition of primary radicals (Scheme 2) to monomers **1** is not always regioselective. For example, in the reaction of benzoyloxy radicals **23** with styrene^{109,110} tail addition (80%), head addition (6%), and addition (in end effect substitution) to the styrene benzene ring (14%) can be observed. Deliberate synthesis of head-to-head polymers and their properties were reviewed¹¹¹ by Vogl and coworkers.

Propagating organic radicals are more or less planar (sp^2 hybridized) and, consequently, the polymers formed by RP are generally atactic. Detailed treatments of the stereochemical aspects of the propagation step in RP are available.^{54,62}

In general, polymers produced by RP have higher densities than the starting vinylic monomers. As a consequence, polymerization is accompanied by volume contraction (up to 20% depending on monomer), which can be a significant problem in adhesive, coating, mold-filling (dental fillings), and other applications where volume change (shrinkage) is undesirable. However, only very low shrinkage or even a net increase in volume is observed with special cyclic monomers^{2,54,112} undergoing radical ring-opening polymerization

(ROP). Each propagation step of ROP results in ring-opening. For example, the ROP of the bicyclic 2-methylene-1,3-dioxepane **44** (Scheme 15) occurs with a small (0.5%) volume expansion. This expansion is probably due to the conversion of the more dense structure of the crystalline monomer **44** into the less dense structure of the amorphous polymer **45**.¹¹³

At low conversion, the overall rate of polymerization R_p is kinetically first order in monomer and half order with respect to initiator (5), for definition of f see (1).

$$R_p = -\frac{d[M]}{dt} = k_p \left(f \frac{k_d}{k_t} \right)^{1/2} [M][I]^{1/2} \quad (5)$$

The kinetic chain length ν (6) is defined as the average number of monomer molecules polymerized by each initiating radical. It can be expressed as the rate of chain propagation divided by the sum of the rates of all of the chain termination processes. In the case of termination by disproportionation, it equals the number average degree of polymerization $\bar{X}_n$.

$$\nu = \frac{k_p[M]}{2(fk_d k_t[I])^{1/2}} \quad (6)$$

Equations (5) and (6) show that increasing the concentration of the initiator will indeed increase

the rate of polymerization, although not linearly, but will inevitably result in a polymer of shorter chain length.

The propagation step is potentially a reversible process. Polymerization can occur spontaneously only when the associated free-energy change ΔG_p is negative. ΔG_p is expressed in (7) where ΔH_p represents the enthalpy and ΔS_p represents the entropy change upon propagation.

$$\Delta G_p = \Delta H_p - T\Delta S_p \quad (7)$$

Each monomer can be characterized by a ceiling temperature T_c at which, for a given monomer concentration, the polymerization rate becomes zero.

Common monomers such as ethene, vinyl acetate, and acrylates have very high T_c 's ($>400^\circ\text{C}$) and depropagation does not occur under viable polymerization conditions. Styrene has a significantly lower ceiling temperature and depropagation must be taken into account above 250°C . The addition of a substituent to the α position of a vinylic monomer greatly reduces T_c . α -Methylstyrene can, for example, be polymerized only at room temperature or below.

2.5 Copolymerizations

Copolymerization of two or more monomers by RP is commonly used in industry to tune the properties of commercial polymers. For example, addition of the polar monomer acrylonitrile to styrene affords a copolymer with much improved oil and grease resistance. Many industrial polymers are prepared from two, three, or even more monomers. In addition to varying chain length and stereochemistry, copolymers differ in their composition (the relative amounts of each monomer incorporated into the copolymer), sequence distribution (the way in which these monomer are arranged within the chain), and architecture (linear or graft or branched) (Figure 5).

Different monomers lead to different radicals, and the relative rates of propagation depend on the steric and electronic properties of both monomer and radical. Therefore, at any given time the ratio at which the monomers are incorporated into the polymer is not equal to their ratio in the monomer mixture. Hence, both the composition

Figure 5 Different types of copolymers.

Scheme 16 Copolymerization of two monomers M_A and M_B .

of the monomer feed and copolymer will change with conversion and, consequently, batch copolymers will in most cases not have homogeneous composition at the molecular level.

Several kinetic models of radical copolymerization have been developed (e.g., terminal, penultimate, complex dissociation, and so on) and details can be found in the monographs of Matyjaszewski and Davis⁶² or Moad and Solomon.⁵⁴ Here, only the simplest, the so-called terminal model¹¹⁴ of radical copolymerization, will be briefly discussed. This model describes the copolymer composition for the majority of systems reasonably well but is less suitable for copolymerization kinetics, for which the penultimate model is more appropriate.

The terminal model assumes that the reactivity of the polymer radical depends only on the nature of its terminal monomer unit: that is, the penultimate unit on the macroradical does not affect its reactivity. Accordingly, the kinetics of copolymerization of two monomers M_A and M_B is determined by the relative rates of four propagation reactions characterized by four propagation rate constants k_{pAA} , k_{pAB} , k_{pBB} , and k_{pBA} (Scheme 16).

The composition of a copolymer formed at a given instant from a specific monomer mixture is

Table 3 Selected terminal model reactivity ratios.

Monomer M _A	Monomer M _B	<i>r</i> _{AB}	<i>r</i> _{BA}
Methyl methacrylate	Ethyl methacrylate	1.0	1.0
Styrene	Acrylonitrile	0.4	0.05
Styrene	Maleic anhydride	0.02	0.01
Vinyl chloride	Vinyl acetate	2.0	0.3
Vinyl acetate	Styrene	0.05	50.0

Source: Data from Ref. 67.

described by the Mayo–Lewis equation¹¹⁴ (8):

$$\frac{F_A}{F_B} = \frac{f_A}{f_B} \left(\frac{r_{AB}f_A + f_B}{f_A + r_{BA}f_B} \right) \quad (8)$$

where $F_A = (1 - F_B)$ and $f_A = (1 - f_B)$ are the instantaneous mole fractions of monomer M_A in the polymer and in the monomer mixture, respectively, and $r_{AB} = k_{pAA}/k_{pAB}$ and $r_{BA} = k_{pBB}/k_{pBA}$ are the monomer reactivity ratios.

Using this equation, it is possible to predict the copolymer composition for a given monomer mixture from just two parameters, namely, the reactivity ratios (sometimes also called *copolymerization parameters*) r_{AB} and r_{BA} , which are available for many monomers.⁶⁷ However, the published data often spans a considerable range. Additionally, several empirical methods⁵⁴ for the prediction of reactivity ratios are available, the most widely used being the *Q*–*e* scheme^{115,116} of Alfrey and Price. A few values of the reactivity ratios are given in Table 3 for illustration.

As seen from Table 3, the values of r_{AB} and r_{BA} are generally different. The special case where $r_{AB} = r_{BA} = 1$ occurs with monomers that are very similar, such as the homologous esters of acrylic or methacrylic acids. For this case, the product is a random copolymer and the monomers are incorporated into the copolymer according to their proportions in the monomer mixture. In cases where $r_{AB} < 1$ and $r_{BA} < 1$, a tendency toward alternation is observed because cross-propagation is favored over homo-propagation. When r_{AB} and r_{BA} approach zero, an alternating copolymer is obtained. A well-known example is the styrene–maleic anhydride copolymer. The situation where r_{AB} and r_{BA} are both greater than 1 is rare, and copolymers with larger blocks consisting of M_A and M_B are the result. In cases where $r_{AB} < 1$ and $r_{BA} < 1$ (or $r_{AB} > 1$ and $r_{BA} > 1$), there always exists exactly one so-called *azeotropic composition* of the monomer mixture at

which the composition of the formed copolymer is the same as that of the monomer mixture. The azeotropic composition is given by (9).

$$\frac{[M_A]_{\text{Azeotrop}}}{[M_B]_{\text{Azeotrop}}} = \frac{1 - r_{AB}}{1 - r_{BA}} \quad (9)$$

Its existence is of significant industrial importance. In fact, a copolymer without compositional heterogeneity can be prepared by conducting simple batch copolymerization if the ratio of both monomers fulfills (9). Analogous composition equations^{117,118} for (rare) azeotropic composition of three or four monomers have also been developed.

Finally, when $r_{AB} > 1$ and $r_{BA} < 1$ (or $r_{AB} < 1$ and $r_{BA} > 1$), one monomer will always be preferentially incorporated into the copolymer. These copolymerizations have no azeotropic composition. Of course, kinetic treatment of ternary⁵⁴ (three monomers) or even quaternary (four monomers) copolymerization is significantly more complicated. For example, nine distinct propagation reactions and six reactivity ratios must be considered in the terminal model for three monomers.

2.6 Chain Transfer and Chain Transfer Agents

A chain transfer reaction is the interaction of the propagation radical with a nonradical species (T) to produce a dead polymer chain and a new radical (T*) capable of initiating a new propagating chain (refer Scheme 2). Details on the theory can be found in the article¹¹⁹ by Chieftain and Gizzard or that by Corner.¹²⁰ In principle, chain transfer can occur with any species present in the polymerizing system (initiator, solvent, monomer, polymer, adventitious impurity, or deliberately added chain transfer agent) and it always causes a reduction in $\bar{X}_n$, the number-average degree of polymerization.

Table 4 Transfer constants (k_{tr}/k_p) at 50 °C.

	Styrene	Methyl acrylate	Methyl methacrylate	Vinyl acetate
Benzene	2×10^{-6}	2×10^{-5}	4×10^{-6}	1×10^{-4}
Toluene	1×10^{-5}	1×10^{-4}	2×10^{-5}	2×10^{-3}
Ethyl acetate	5×10^{-4}	6×10^{-5}	1×10^{-5}	2×10^{-4}
CCl ₄	1×10^{-2}	2×10^{-4}	2×10^{-4}	0.8
1-Butanthiol	20	1.5	0.6	50

Source: Data from Ref. 67.

Furthermore, chain transfer to the polymer results in branching or potentially cross-linking. For example, intramolecular chain transfer (backbiting) leading to branching is observed during the RP of ethylene.¹²¹ Quantitatively, the efficiency of chain transfer to a given species is characterized by its transfer constant $C_{tr} = k_{tr}/k_p$. For efficient chain transfer to occur, the rate constant of reinitiation (k_{tr}) by T^* must be equal to or greater than that for propagation (k_p) (refer Scheme 2). The magnitude of the transfer constant depends on the structure of both the transfer agent and the radical. Since the propagation and transfer reactions show similar temperature dependence, chain transfer constants change only slightly with temperature. The transfer constants for variety of monomers and transfer agents can be found in the literature.⁶⁷ Most organic compounds have low transfer rates, and transfer is important only when they are present in high concentration, that is, as solvent. Table 4 illustrates the C_{tr} values for a few typical solvents and chain transfer agents at 50 °C.

Deliberately added chain transfer agents (T) with large C_{tr} are often used in industrial polymerizations to control (limit or reduce) the molecular weight and molecular weight distribution of polymers. The influence of chain transfer on $\bar{X}_n$ can be described by the Mayo equation¹²² (10):

$$\frac{1}{\bar{X}_n} = \frac{1}{\bar{X}_{n0}} + C_{trT} \frac{[T]}{[M]} \quad (10)$$

where $\bar{X}_n$, $\bar{X}_{n0}$ are the number-average degree of polymerization in the presence or absence of chain transfer, respectively, and C_{trT} is the chain transfer constant of T.

The added transfer agent is said to behave ideally if its chain transfer constant is equal to unity. In this case, the ratio of the rates at which the monomer and transfer agent are consumed by the growing radicals is constant and equal to the ratio of the molar concentrations of the monomer to

transfer agent. This means that $\bar{X}_n$ remains constant throughout the polymerization. On the other hand, a transfer agent with $C_{trT} \gg 1$ will be rapidly consumed in early stages of the polymerization. In the case of $C_{trT} \ll 1$, the ratio $[T]/[M]$ increases with conversion, leading to a decrease in $\bar{X}_n$ as the polymerization progresses. Polymers with a broad molecular weight distribution result in both cases. Continuous addition of the monomer or transfer agent during polymerization to maintain a constant the $[T]/[M]$ ratio may help to overcome these problems. The control of the molecular weight of the polymer with the transfer agent translates into control of the viscosity of the reaction mixture and, through mitigation of the gel or the Norrish–Trommsdorff effect,^{123,124} into control of the polymerization rate and exothermicity.

Typical chain transfer agents used in industrial synthesis of variety of polymers (PS, poly (methyl methacrylate) PMMA, ABS, acrylic-, styrene-butadiene-, or acrylonitrile-butadiene copolymers) include mercaptans such as *n*-octyl mercaptan, *n*-dodecyl mercaptan, or 2,2-dimethyldodecyl mercaptan (*tert*-dodecyl mercaptan). Technical information¹²⁵ on mercaptans, as well as examples¹²⁶ of their use as chain transfer agents, can be found on the web site of their producers. Chain transfer with *n*-dodecyl mercaptan **46** in the styrene polymerization is exemplified in Scheme 17.

Primary mercaptans are more active chain transfer agents than secondary or tertiary ones. Apolar mercaptans are lipophilic and odiferous compounds of moderate toxicity. Examples of water-soluble and practically odor-free chain transfer agent are mercaptoacetic acid (thioglycolic acid) and 2-mercaptoethanol. Moreover, these agents introduce functionalities (COOH or OH) into the chains providing access to monofunctional^{120,127} polymers. A special case of chain transfer is the reversible addition fragmentation chain transfer (RAFT), which is an important method of controlled RP

Scheme 17 Polymerization of styrene with chain transfer with *n*-dodecylmercaptan.

(see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).

2.7 Chain Termination

The propagating radicals in RP add a monomer unit every ~ 1 ms on average and typically terminate after about ~ 1 s. Polymeric chains with high $\bar{X}_n$ are formed during this short time. Termination of growing radicals occurs via coupling (k_{tc}) or disproportionation (k_{td}) (Scheme 18). The corresponding rate constants are very high, $k_t \sim 10^7$ – 10^9 M $^{-1}$ s $^{-1}$, approaching the diffusion-controlled limit.

Sterically undemanding radicals terminate preferentially through coupling (styrene), whereas radicals derived from 1,1-disubstituted monomers generally undergo disproportionations (methyl methacrylate). The self-termination of growing macroradicals is a diffusion-controlled process. Therefore, the termination rate constants depend strongly on the chain lengths, and k_t decreases with increasing viscosity of the polymerizing mixture. The increase of viscosity in bulk polymerizations at medium to high conversions slows down the movement of large chains to such a level that their self-termination becomes very slow. On the other hand, monomer molecules may still diffuse rapidly. As a consequence, an autoacceleration phenomenon known as the Norrish–Trommsdorff or gel effect^{123,124} may occur.

Macroradicals can also terminate by reaction with radicals derived from the initiator. Finally, another very important source of termination reactions is the deliberately added molecules called *inhibitors* or oxygen (oxygen inhibition).

2.7.1 Inhibitors

Pure monomers must be protected during storage from polymerization by mixing them with small amounts of polymerization inhibitors, species able to rapidly and efficiently scavenge propagating and/or primary radicals. Moreover, the presence of inhibitors is also necessary during the synthesis and purification (e.g., distillation) of monomers. In fact, a distinction between storage and in-process stabilizers is sometimes made. An ideal inhibitor will prevent polymerization during what is termed an *induction period*. Once consumed, polymerization proceeds at a normal rate. Species that do not show a distinct induction period but rather slow down polymerization are called *retarders*. This topic was reviewed by Bovey and Kolthoff¹²⁸ and Tüdös and Földes-Berezsnich.¹²⁹ Common inhibitors include stable radicals such as galvinoxyl, nitroxide radicals, diphenylpicrylhydrazyl, phenols, quinones, nitrones, nitro and nitroso compounds, phenothiazine, and salts of transition metals which can trap C-centered radicals by electron transfer. Examples of industrially important inhibitors (Scheme 19) are *p*-methoxyphenol **47**, 2,4-di-*t*-butyl catechol **48**,

Scheme 18 Termination of polystyrene macroradicals by combination and disproportionation.

Scheme 19 Examples of polymerization inhibitors.

Scheme 20 Inhibition of polymerization with *p*-methoxyphenol.

phenothiazine **49**, *N,N*-diethylhydroxylamine **50**, salts of *N*-nitroso phenylhydroxylamine **51**, and 4-hydroxy-TEMPO **52**. An example of a retarder is 2,6-di-*t*-butyl-7-phenyl quinone methide **53**, which is used in combination with nitroxide radicals as a storage stabilizer¹³⁰ for radiation-curable coating or ink compositions.

The phenolic inhibitors **47–48**, which are used mostly as storage stabilizers, require^{131,132} traces of oxygen in order to be fully effective. The phenols themselves are rather poor scavengers of C-centered radicals. The latter, however, react very rapidly with oxygen, affording peroxy radicals **54** which are efficiently transformed into nonradical products, namely, hydroperoxides **55** and cyclohexadienones **56**, by reaction with phenols (Scheme 20).

For this reason, the oxygen content in large storage tanks containing acrylic or methacrylic acid and *p*-methoxyphenol (100–200 ppm) as polymerization inhibitor is continuously monitored and maintained at a specific level. An illustrative case of a runaway acrylic acid polymerization caused by insufficient inhibition was reported¹³³ by Levy and Penrod.

On the other hand, phenothiazine **49** is a good hydrogen donor to both C-centered and peroxy radicals and, therefore, an excellent inhibitor^{132,134} even in the absence of oxygen.

The liquid and rather volatile (bp 125 °C) *N,N*-diethylhydroxylamine **50** is used as in-process inhibitor in distillations of monomers such as styrene, divinylbenzene, isoprene, and butadiene.

In precise laboratory work with monomers, the inhibitors are often removed by distillation, by

filtration over a pad of aluminum oxide, or by a suitable extraction procedure. In industrial polymerizations, such purifications would be too expensive. Therefore, in most cases, the inhibitor is not removed but consumed by the additional initiator.

2.7.2 Oxygen Inhibition

RPs are tolerant to protic solvents but suffer from oxygen inhibition when conducted in air-saturated media or under an air atmosphere. The dioxygen molecule, due to its biradical ground state character, reacts with carbon-centered radicals to give peroxy radicals **54**. The rate of this peroxidation reaction is much greater¹³⁵ ($k_{O_2} \sim 10^8\text{--}10^9\text{ M}^{-1}\text{ s}^{-1}$) than the typical rates⁵⁴ of propagation ($k_p \sim 10^2\text{--}10^4\text{ M}^{-1}\text{ s}^{-1}$). Hence, at equal monomer and oxygen concentrations, the peroxidation would be $10^4\text{--}10^7$ faster than propagation (Scheme 21). The concentration of dissolved oxygen in monomers is on order¹³⁶ of 10^{-3} M , whereas the concentration of monomers is generally in the range of 0.1–10 M. Even so, the vast majority of carbon-centered radicals in air-saturated monomers are converted into the peroxy radicals **54**. The latter add only very sluggishly¹³⁷ ($k_{OO} \sim 0.1\text{--}3\text{ M}^{-1}\text{ s}^{-1}$), in what is now a rate-determining step, to monomers affording new C-centered radicals. As these C-radicals react again preferentially with oxygen, the result is an alternating copolymer with oxygen. The normal polymerization will be possible only when the majority of dissolved oxygen is consumed. This can

Scheme 21 Oxygen inhibition.

occur if the rate at which it is replenished from the air-exposed surface is sufficiently low. The oxygen copolymers are polymeric peroxides that are thermally and photochemically unstable and thus impair the properties of the final polymer. Moreover, peroxy radicals¹³⁸ abstract H atoms from the surrounding substrates (PH) to yield new radicals and the hydroperoxides **55**. The latter are potential sources of new radicals, which may further complicate the polymerization.

The influence of oxygen on radical and other polymerizations has been reviewed by Bahanu and Kishore.¹³⁹ To prevent these detrimental effects, measures must be taken to exclude oxygen by conducting the polymerization under vacuum or nitrogen, or in a refluxing solvent. Oxygen inhibition is a serious problem and is much more difficult to avoid in the photopolymerization of thin films and coatings due to the very large surface. Here, it leads to incompletely cured, tacky surfaces with poor mechanical properties. Different methods to overcome oxygen inhibition in these applications were reviewed¹⁴⁰ by Scranton and coworkers. Latest strategies involve an admixture of oxygen-scavenging additives,^{141,142} use of monomers with high functionality,¹⁴³ or singlet oxygen¹⁴⁴ sensitizers. It should be noted that oxygen inhibition is not a problem for every RP process. The radical thiol–ene click reaction, which is becoming an important tool for polymer synthesis,^{145–147} is much less sensitive to oxygen.

3 POLYMERIZATION PROCESSES

3.1 General Comments

Rather than listing the complete literature dealing with industrial polymerization processes and the

related reactor technology, we refer the reader to good introductory texts.^{148–150}

Industrial polymerizations differ from the processes used for synthesis of low molecular compounds in several respects. For one, it is usually not possible to purify the final polymer by standard distillation or crystallization techniques. Polymers obtained by classical RP are always mixtures of macromolecules with varying degrees of polymerization and deviation from the idealized structure. Separation of these mixtures is not possible on an industrial scale. Elimination of residual monomers, initiators, or solvents can also be a difficult and costly task requiring special methods and equipment.

The properties of the polymer, for example, its molecular weight distribution which influences its mechanical properties and processability, often strongly depend on the method (e.g., suspension polymerization or EP) by which it is prepared.

An important feature of polymerization in solution or in a melt is the dramatic increase, often by several orders of magnitude, of the viscosity during the reaction. This viscosity increase is the cause of the autoacceleration effect called the Norrish–Trommsdorff effect.^{123,124} It complicates mixing and pumping of the reaction mass and significantly reduces the rate of heat transfer and, therefore, the efficiency of the reactor cooling. Temperature control of industrial polymerizations is a very critical task because of the highly exothermic nature of RPs. In many cases, a rapid and, therefore, almost adiabatic runaway polymerization would cause temperature increase of many hundreds of degrees,¹⁵¹ leading to serious consequences such as fire, reactor rupture, or environmental contamination. For example,¹⁵² the adiabatic temperature increase at 100% conversion of monomer into polymer is

1810 °C for ethylene, 721 °C for acrylonitrile, 542 °C for vinylchloride, and 336 °C for styrene.

In fact, the average heat of polymerization ΔH_p of a vinylic monomer is about -82 kJ mol^{-1} , which is the difference between the sum of the energies of the two C–C single bonds ($\sim 2 \times 346 \text{ kJ mol}^{-1}$) formed in the polymer and the bond energy of a C=C bond ($\sim 610 \text{ kJ mol}^{-1}$) of the monomer. The actual heats of polymerization vary as a result of secondary effects such as steric strain in the polymer or differences in the resonance stabilization or hydrogen bonding, and solvation between the monomer and polymer. For example, ΔH_p varies¹⁵³ from -35 kJ mol^{-1} for α -methyl styrene to -163 kJ mol^{-1} for tetrafluoroethene (25 °C, liquid monomer $\rightarrow$ solid polymer). Detailed discussion of the thermodynamics of polymerization is provided in the monograph¹⁵³ of Sawada. Data on the heats, entropies, free-energy changes, and ceiling temperatures of polymerization of many monomers can be found there or in the *Polymer Handbook*.⁶⁷

3.2 Polymerization Techniques

The different polymerizations according to the classification on Figure 4 can be carried out in several ways: bulk polymerization, precipitation polymerization, solution polymerization, slurry polymerization, gas-phase polymerization, suspension polymerization, or EP. The polymerization techniques that are important for industrial RP are briefly highlighted.

3.2.1 Bulk Polymerization

The only components of a bulk polymerization mixture are monomers, the initiator, and, optionally, a chain transfer agent. The initiator may be omitted in the case of thermal autoinitiation of styrene. The main advantage of bulk polymerization is that a very pure polymer is produced. Furthermore, as the polymer is not diluted, the volume yield of the polymer is high. However, the high increase of viscosity during the polymerization makes the stirring and removal of the heat of polymerization difficult. A special type of bulk polymerization is precipitation polymerization. Here, the polymer is not soluble

in its own monomer (e.g., PVC in vinylchloride) and precipitates during the polymerization. Examples of polymers prepared by bulk polymerization are PMMA, general-purpose (or crystalline) PS, and LDPE.

3.2.2 Solution Polymerization

Solution polymerization is related to bulk polymerization but the components are dissolved in a suitable solvent. Both the heat generation and viscosity of the polymerization mixture are lower because of dilution. The thermal control of the reactor is also facilitated because the lower viscosity allows more efficient cooling. Optionally, cooling can be achieved by refluxing the solvent. The drawback of solution polymerization is that the polymer must be freed from the solvent if it is needed in pure form.

3.2.3 Suspension Polymerization

Suspension polymerization enjoys the advantages of bulk polymerization but is not plagued with problems of high viscosity and difficult thermal control. In this technique, pure monomers containing the dissolved initiator and, optionally, chain transfer agent are dispersed (suspended) in a continuous water phase (1–1.5 times by mass) in form of small droplets in the size range of 50–1000 μm . Both monomer and coreactants must be insoluble in water. The dispersion of the organic (or oil) phase in water is effected by stirring in the presence of added surfactants. Frequently used surfactants are amphiphilic polymers such as poly(vinyl alcohol), partially hydrolyzed poly(vinyl acetate), or hydroxypropyl methyl cellulose. Micronized inorganic powders such as CaCO_3 , MgCO_3 , or $\text{Ca}_3(\text{PO}_4)_2$ are also used. The advantage of these inorganic “pickering dispersants” is that they can be easily removed from the polymer by treatment with diluted acid. The droplet size and size distribution are complex functions of the type and concentration of the dispersant, stirring parameters, reactor, and stirrer geometry, as well as the physical properties of the dispersed and continuous phases. From a kinetic point of view, each droplet behaves as a small bulk polymerization reactor. The droplets are transformed during

the polymerization into rigid spherical polymer particles which are easily isolated by filtration. The main advantage of suspension polymerization is the easy thermal control of the reactor and virtually constant viscosity of the reaction mass as a whole. The purity of polymers prepared by this technique is higher than that obtained in EP and is comparable to that of bulk or solution polymerization. Examples of polymers made by suspension polymerization are PS and PMMA. The most important production process¹⁵⁴ for PVC is suspension polymerization of vinylchloride in pressurized (8–12 bar, because of the low boiling point of vinylchloride) reactors. PVC is not soluble in vinylchloride and precipitates in the monomer droplets which are finally transformed into porous polymer particles (“powder” suspension polymerization).

3.2.4 Emulsion Polymerization

EP, like suspension, mini emulsion, and microemulsion polymerization, is a type of heterogeneous polymerization. It should be noted that heterogeneous polymerizations are not only radical in nature. Heterogeneous polymerizations in aqueous dispersed media have been reviewed¹⁵⁵ by Charleux and Ganachaud.

EP provides polymer particles of 50–1000 nm dispersed in a continuous medium, most often water. Such polymeric dispersions are called *latexes*. Synthetic latexes were known already in 1930s but it was the work during the United States Synthetic Rubber Program¹⁵⁶ (1939–1945) which established EP as a unique and industrially viable technique. In the second half of the twentieth century, the method was further developed and attained a high level of technical and theoretical understanding. Today, about 10% of all synthetic polymers or some 20% of those prepared by RP ($>20 \times 10^6$ tons per year) are made by EP.¹⁵⁷ The process is named *emulsion polymerization* for historical reasons because it was originally targeted with the polymerization of emulsified monomer droplets, and only later it was realized that polymerization occurs not in the monomer droplets but mainly within the monomer-swollen latex particles. Among the abundant literature, the excellent monograph of Herk¹⁵⁸ which covers the history, mechanism, as well as industrial applications of EP; the books of Asua^{150,159}; or the recent

book of Chern¹⁶⁰ which additionally treats the related mini emulsion and microemulsion polymerizations can be highlighted. Therefore, only the key aspects of classical EP will be discussed here. The simplest EP system consists of a continuous aqueous phase, a practically water-insoluble monomer, a water-soluble initiator, and a colloidal stabilizer (emulsifier or surfactant). The monomer is dispersed to form small (0.01–0.1 mm) droplets which are stabilized against coalescence by a layer of surfactant molecules. It is important to note at this point that “water-insoluble” monomers used in EP in reality have a very small but measurable solubility in water: for example, the solubility of styrene at 50 °C is 4.3×10^{-3} M (see p. 78 of Ref. 158 for the water solubility of industrial monomers). If the concentration of the surfactant is above the critical micelle concentration (CMC), the formation of micelles occurs. These generally spherical micelles with a diameter of a few nanometers contain $\sim 10^2$ surfactant molecules and are swollen by the monomer which migrates from the “reservoir” droplets through the water phase. The number of micelles ($\sim 10^{17} - 10^{19} \text{ l}^{-1}$) is many orders of magnitude higher than the number of monomer droplets ($\sim 10^{10} \text{ l}^{-1}$). Consequently, the surface area of the micelles is 3–5 orders of magnitude larger than that of the droplets. The hydrophilic primary radicals formed in the water phase from the water-soluble initiator (e.g., ammonium persulfate) do not enter the lipophilic micelles. They preferentially add to and propagate with the monomer dissolved in water until the resulting oligomeric radicals are lipophilic enough to enter (nucleate) the micelles. Nucleation of the monomer droplets is insignificant because of the much larger surface of the micelles compared to the droplets.

Rapid propagation then follows in the monomer-swollen micelles leading to latex particles in a process called *heterogeneous nucleation*. A different process called *homogeneous nucleation* occurs if the amount of surfactant is below the CMC. In this case, the oligomeric waterborne radicals continue to propagate until they became insoluble enough that they undergo coil-to-globule transition. The resulting hydrophobic globules are swollen with monomer and became latex particles, too. Both heterogeneous and homogeneous nucleation may be operative in a given system. Monomer droplets, monomer-swollen micelles, and monomer-swollen latex particles coexist during the

Figure 6 Emulsion polymerization.

nucleation phase. As the polymerization proceeds, the number of micelles decreases as they are either transformed into latex particles or dissociate to provide surfactant to stabilize the increasing surface area of the latex particles or globules formed by homogeneous nucleation. At the end of nucleation (monomer conversion of 5–10%), all micelles have disappeared and 10^{17} – 10^{18} latex particles per liter are present. They are now the main sites of polymerization. New monomer diffuses from the droplets into the latex particles to replace the monomer consumed there through polymerization. Consequently, the size of latex particles increases and that of droplets decreases until they disappear completely. The polymerization then continues in the monomer-swollen latex particles until the monomer is depleted. The result is a polymeric dispersion in water or a latex (Figure 6).

As the change of viscosity during the course of EP is very small (similar to suspension process), the control of the polymerization reactor is simplified. EP never proceeds to 100% conversion, but leaves some residual monomer in the waterborne polymer that must be removed. This can be performed either via stripping with steam or nitrogen, or through postpolymerization by addition of fresh initiator.

It is important to note that the basic mechanism of RP is the same in bulk, suspension, and EP. However, the distinctive feature of EP is the radical compartmentalization. In fact, the radicals that are situated in different particles cannot terminate by bimolecular termination. Because of the small size of the latex particles, only one propagating radical is inside at a given time. Hence, the polymer chain in the particle grows until a new radical enters and terminates with the growing one. Therefore, on average, 50% of particles contain one radical and the rest none. Nevertheless, due to the enormous number

of particles, the overall radical concentration in the latex is about one order of magnitude higher than in a typical bulk polymerization (10^{-8} M). Consequently, the polymerization rates are higher in EPs as compared to bulk or suspension process. Radical compartmentalization also allows longer radical life times, resulting in polymer chains of a higher degree of polymerization. The lifetime of the propagating radicals in the particles is inversely proportional to the frequency at which new radicals enter the particles and terminate with the growing ones. The entering frequency for a given concentration of the initiator decreases with the number of particles. Hence, it is possible to increase the rate of polymerization and the molecular weight of the polymer by simply increasing the number of particles, for example, by changing the monomer to surfactant ratio.

The continuous phase in conventional EP is water. Water-soluble monomers (e.g., acrylamide) can be polymerized via *inverse EP*. In this process, an aqueous solution of the water-soluble monomer and surfactant is dispersed in an organic phase (e.g., hexane) and the polymerization is initiated by lipophilic initiators. The process proceeds via a mechanism similar to aqueous EP and results in a dispersion of an aqueous solution of water-soluble polymer in an organic phase.

About 50% of emulsion polymers are commercialized as waterborne dispersions. It is important to note that emulsion polymers have in common the same state of aggregation but are diverse in chemical composition. A comprehensive overview of waterborne polymeric dispersions together with their applications and markets is available in the monograph¹¹ of Urban and Takamura and of Daniel and Pichot.¹² The main waterborne dispersions and their respective markets are shown in Table 5.

Table 5 Waterborne polymer dispersions by product class.

-
- Styrene–butadiene copolymers (paper coatings, paperboard, carpet backing, adhesives and sealants, additives for mortar and bitumen), 37%.
 - Polyacrylates, polymethacrylates, styrene–acrylate copolymers (paints, coatings, adhesives, inks, paper, and leather coatings), 30%.
 - Vinyl acetate homo- and copolymers (paints, adhesives for paper and wood), 28%.
-

A substantial part of emulsion polymers is commercialized as dry products. Examples are styrene–butadiene rubber (SBR), acrylonitrile–butadiene rubber (nitrile rubber), about 75% of ABS copolymer, a small part of PVC, water-redispersible powders¹¹ for the construction industry, and polymeric modifiers¹¹ for plastics (e.g., impact modifiers, processing aids, rheology modifiers, and so on). Diverse techniques for the isolation of the polymer from the dispersion are available: for example, direct spray-drying of the emulsion or its coagulation followed by drying of the filter cake.

Standard laboratory formulations for EP contain water, the monomer, the initiator, and the surfactant. Commercial recipes are often much more complicated, containing up to 20 components. A large number of monomers are used in EP either alone to give homopolymers or, more frequently, as mixtures to provide copolymers. In general, random copolymers are obtained with an inhomogeneous monomer distribution throughout the chains. Individual monomers impart specific properties to the final polymer. Acrylonitrile, for example, improves

solvent resistance, while vinyl chloride improves fire retardancy and acrylates provide good stability against light and heat. An important polymer property that must be controlled is the glass transition temperature T_g , which strongly influences the film formation from a latex and the mechanical properties of the film. The T_g of a copolymer can be estimated with the simple Fox equation (11) or with recently developed¹⁶¹ more sophisticated models.

$$\frac{1}{T_g} = \frac{W_{M1}}{T_{g1}} + \frac{W_{M2}}{T_{g2}} + \dots + \frac{W_{Mn}}{T_{gn}} \quad (11)$$

where T_g refers to the copolymer, T_{g1} , T_{g2} , ... refer to the individual homopolymers, and W_{M1} , W_{M2} , ... are the weight fractions of monomers M1, M2, ... in the copolymer.

In addition to the principal monomers that make up largest part of the latex (e.g., butadiene, styrene, and so on), small amounts (typically 2–5% based on the dry polymer) of the so-called functional monomers are often used. These important comonomers contain functional groups (COOH, NH₂, OH) that impart special properties to both the colloidal system and the polymer. As EP usually provides polymers of impractically high molecular weight, chain transfer agents, usually mercaptans, are often used. Other common additives include electrolytes (buffers) and metal ion sequestering agents. A typical list of the components of an industrial EP formulation is shown in Table 6.

Table 6 Components of an industrial emulsion polymerization recipe.

-
- **Monomers (50–55 wt%)**
Principal monomers leading to high T_g : methyl methacrylate, styrene, acrylonitrile, vinyl chloride, vinyl acetate
Principal monomers leading to low T_g : methyl acrylate, 2-ethylhexyl acrylate, *n*-butyl acrylate, 1,3-butadiene
Functional monomers: acrylic and methacrylic acid, itaconic acid, fumaric acid, 2-hydroxyethyl acrylate, acrylamide
 - **Initiators (0.3–0.5 wt%)**
Thermal initiators: sodium, potassium or ammonium persulfate, water-soluble azo-compounds
Redox initiators: *t*-BuOOH or persulfate + Na₂S₂O₅
 - **Surfactants (0.5–3 wt%)**
Ionic surfactants: sodium lauryl sulfate, sodium or potassium salts of fatty acids (soaps), salts of alkylbenzene sulfonates
Nonionic surfactants: *O*-polyoxyethyleneated long-chain alcohols or alkylphenols
 - **Chain transfer agents:** mercaptans
 - **Sequestering agents:** ethylenediamine tetraacetic acid (EDTA) (for complexing of adventitious metal ions, to prevent among other things their uncontrolled reaction with the redox initiator)
 - **Electrolytes:** alkali metal phosphates (to control the pH)
 - **Water, sometimes deionized (45%)**
-

3.2.5 Mini- and Microemulsion Polymerization

The majority of dispersion polymers are prepared by conventional EP. However, two variants of classical EP, *mini-* and *microemulsion polymerizations*, are of industrial interest and will, therefore, be briefly mentioned. A comprehensive discussion of the physicochemical and technological aspects of mini emulsion polymerization can be found in the monograph¹⁶² of Mittal. The size of the monomer droplets in a mini emulsion polymerization^{160, 162–166} is significantly reduced (30–500 nm) relative to that in EP ($>10^4$ nm). These small droplets are obtained by intensive homogenization in the presence of a surfactant and a small amount of extremely hydrophobic costabilizer, sometimes called *hydrophobe* (e.g., hexadecane or cetyl alcohol). The hydrophobe cannot migrate through the aqueous phase and thus prevents the diffusion of monomer molecules from smaller droplets to larger ones (Ostwald ripening) through establishment of counteractive osmotic pressure in the smaller droplets. As a result, kinetically stable mini emulsions are obtained which can be polymerized by both water- and oil-soluble initiators. In contrast to the classical EP, the locus of polymerization in a mini emulsion is within the emulsion droplets. The resulting latex can be viewed as a polymerized copy of the original mini emulsion. An important consequence for industry is that water-insoluble compounds (monomers, polymers, inorganic solids, pigments, carbon black, additives, etc.) can be directly incorporated/encapsulated^{165, 166} into the polymer particles by dissolving/dispersing them in the monomer prior to polymerization. A practical industrial example is the encapsulation of light stabilizers¹⁶⁷ to render them easily dispersible in coating formulations. This is not possible via classical EP since the monomer and the species dissolved/dispersed in it need to diffuse through the aqueous phase to the growing polymer particles. Mini emulsion polymerization bears some similarity to suspension polymerization. In both cases, the polymerizing droplet behaves as an individual batch reactor. The main difference is in the size and stability of the particles. Ostwald ripening is much less important in suspension polymerization because of the very large size of the particles; hence, addition of hydrophobes is not necessary.

The monomer droplets are even smaller (1–30 nm) in microemulsion polymerization.^{160, 168–171} Microemulsions are thermodynamically stable, isotropic, transparent, or translucent systems which are obtained upon intensive homogenization using a combination of an anionic surfactant (e.g., sodium dodecyl sulfate) and a nonionic cosurfactant (e.g., 1-pentanol). This special surfactant system creates an interfacial tension at the oil/water interface close to zero. The high amount of surfactant in microemulsion formulation leads to a complete surfactant coverage of the droplets. As in mini emulsion polymerization, the locus of polymerization is within the emulsion droplets. The result is very small (~ 5 –50 nm) polymer particles in coexistence with empty micelles. A particle contains only a small number of polymeric chains having a very high molecular weight not achievable via conventional emulsion or mini emulsion polymerization. Potential applications^{160, 171} of microemulsion polymerization include the synthesis of ultrafine latex particles, water-soluble polymers with very high molecular weights for use as flocculants, nanostructured porous materials, functionalized colloidal particles, and transparent colloidal systems for photochemical applications.

3.3 Types of Industrial Polymerization Reactors

Polymer reaction engineering along with the design of polymerization reactors is a huge discipline on its own. The excellent book¹⁵⁰ of Assua, the handbook¹⁴⁸ of Meyer and Keyrentjes, or the chapter of Cunningham and Hutchinson in Ref. 62 is recommended as introductory reading. Polymerization reactors can be grouped according to the method by which the reactants are added to the reaction vessel (Figure 7).

- In a *batch reactor*, all the reactants are charged to the reaction vessel at the beginning and no material is added to or removed from the reactor during polymerization. After its completion, the contents are discharged and the reactor is prepared for the next batch. Batch reactors are the simplest to operate, but offer the least control over the polymerization. Thus, copolymerization of monomers with different reactivity ratios or

Figure 7 Types of reactors commonly used in radical polymerization.

outside the azeotropic monomer feed composition will result in a broad distribution of copolymer composition. On the other hand, batch reactors are readily adaptable to new set of reaction conditions and to new products.

- In a *semibatch* (or semicontinuous) reactor, the starting materials can be added, and/or the products removed, during the polymerization. Often, only a portion of the total amount of reactants is initially charged into the reactor. The polymerization is then started, and more reactants are added during reaction in order to control various parameters such as reaction rate, molecular weight, or copolymer composition distribution. Any reactant can be fed at a selected, individual rate.

Semibatch operation is commonly used to control the copolymer composition distribution. The compositional drift can be substantially reduced by maintaining a constant ratio of monomers in the reactor. Continuous feeding of initiator and monomers in the desired ratio helps to control the molecular weight and to minimize the risk of a thermal runaway reaction because the monomer concentration remains low throughout the polymerization (monomer-starved conditions). Semibatch reactors are widely used in EP: for example, stainless steel vessels ranging in size from 20 to 200 m³ and equipped with a stirrer.

- In a *continuous reactor*, the reactants are introduced and the products as well as unconsumed reactants are withdrawn continuously. Continuous

reactor systems include continuous stirred tank reactors (CSTR), plug flow reactors (PFR), or combinations of both. The polymerization may take place in a single reactor or in a cascade of reactors in which the monomer conversion gradually increases. Continuous reactors are preferred for large-volume polymers with a limited number of variations in polymerization conditions. They offer simplicity of operation, high throughput rates, uniform product quality, and, hence, relatively low operating costs.

4 CONTROLLED REVERSIBLE-DEACTIVATION RADICAL POLYMERIZATION

A 2010 IUPAC recommendation¹⁷² proposes the term *controlled reversible-deactivation radical polymerization* (CRDRP) for polymerizations previously called *controlled radical polymerization* (CRP) or *living radical polymerization* (LRP).

It was the pioneering discovery^{173,174} of living anionic polymerization by Michael Szwarc in 1956 that initiated the rapid development of this field, which has many important applications in industry. Over the years, other controlled and living polymerizations such as group-transfer polymerization, living carbocationic polymerization, living ring-opening metathesis polymerization, or living transition-metal-catalyzed alkene polymerization were developed. A review of the state of the art of controlled and living polymerizations in year 2010 was compiled¹⁷⁵ by Müller and Matyjaszewski. Its preface also gives clear definitions of the sometimes controversial terms “controlled” and “living”.

RP is one of the most important industrial polymerization techniques. However, prior to the mid-1990s, classical RP did not allow the synthesis of polymers with precisely designed molecular architectures such as block, comb, or star copolymers or polymers with defined terminal functional groups or with predetermined and narrow molecular weight distributions. This was, however, possible with the aforementioned nonradical processes. This situation started to change dramatically with the seminal work^{176,177} of Otsu, who in 1982 proposed a reversible deactivation of the growing chains in RP using the so-called iniferters.

Scheme 22 Stable-radical-mediated polymerization.

Today, a plethora of CRP techniques are available. All are based on reversible deactivation of growing chains. Most of these chains are in a dormant form and the period of chain growth of an individual propagating chain may be extended from ~1 s in conventional RP to a few hours in CRDRP. At any given instant, only a small fraction of chains are growing. However, as long as the interconversion of active and dormant forms is rapid compared to propagation, all chains are able to grow at the same rate. Therefore, the polymerization takes on much of the character of a living polymerization. Nonetheless, it is important to note that, even though chain termination and irreversible chain transfer are suppressed to a very low level in such RPs, they are not completely absent.

CRDRP makes possible the synthesis of block copolymers by sequential addition of different monomers. Moreover, if the initiating species are fully consumed prior to any appreciable chain growth, all chains grow at the same rate and the molecular weight distribution of the polymer is much narrower than in a conventional RP.

Presently, the most important CRDRP techniques are the following:

- *Stable-radical-mediated polymerization* (SRMP), which embraces the nitroxide-mediated RP

(NMP) (see **Nitroxide-Mediated Polymerization and its Applications**, note, however, that IUPAC recommends¹⁷² the term *aminoxyl* instead of *nitroxide*) and organometallic-mediated RP (ORMP). The deactivation involves reversible coupling with persistent (stable) radicals (Scheme 22).

- *Atom-transfer radical polymerization* (ATRP) (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**). The deactivation of the radicals involves reversible atom transfer or reversible group transfer catalyzed usually, though not exclusively, by transition-metal complexes (Scheme 23).
- *Degenerate-transfer RP* (DTRP) in which the deactivation of the radicals involves degenerative transfer of a group (or atom). Most prominent is the RAFT polymerization (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**) (Scheme 24).

A detailed treatment of CRDRP is beyond the scope of this article and the reader is referred to recent review articles,^{178–186} monographs,¹⁷⁵ and other articles in this encyclopedia (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**, **Nitroxide-Mediated Polymerization and its Applications**, **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**, **Sb, Bi, Te, and I-Transfer Polymerization and Applications**, and **Fundamentals of Controlled/Living Radical Polymerization**).

4.1 Industrial Applications of Controlled Reversible-Deactivation Radical Polymerization

CRDRP opens completely new possibilities for the design and synthesis of novel materials via RP. As is often the case when revolutionary technologies emerge, very optimistic forecasts of their commercial potential appear. Thus, in 2000 the potential market for CRDRP products was anticipated to exceed 20 billion US\$ per year.¹⁸⁷ Today, 10 years later, the known industrial applications of CRDRP are very few. It is now clear that CRDRP will not replace classical RP for the production of large-volume commodity polymers. However, its potential for the development and production of high-value polymeric specialties remains intact. Possible target products include adhesives, binders, compatibilizers, cross-linkers, dispersants, emulsifiers, leveling agents, lubricants, sealants, and thermoplastic elastomers. These products are expected to find applications in various industries such as aerospace, aircraft and automobile, biomedical and cosmetic, coatings, electronics, home and personal care, and nanotechnology. The industrial obstacles and achievements of CRDRP were reviewed¹⁸⁷ recently in a very detailed manner by Destarac. Not all CRDRP techniques known today are equally well suited for upscaling from small laboratory experiments into large-scale industrial processes. For example, the controlling agent must be cost effective and ecologically sound. Furthermore, residual metals in ATRP or the chemical nature of the end groups (RAFT) may be an issue.

4.1.1 Nitroxide-Mediated Radical Polymerization

NMP can be performed using the combination of a nitroxide radical controller with a conventional radical initiator such as AIBN or dibenzoylperoxide. However, the initiator-to-controller ratio is slightly different for each polymerization system. In fact, due to the cage reactions of the primary radicals, excess of the initiator is required to ensure 1:1 stoichiometry between the nitroxides and *available* primary radicals. For this reason, unimolecular alkoxyamine initiators such as **56** are preferred because their homolysis along the relatively weak¹⁸⁸ ($\approx 110\text{--}140\text{ kJ mol}^{-1}$) NO–R bond affords the nitroxide and initiating radical in exactly 1:1 ratio (Scheme 25).

Yet another possibility is the so-called *in situ* NMP.¹⁸⁹ The required nitroxide radicals are synthesized directly in the polymerizing mixture by addition of radicals generated from conventional initiators to nitric oxide, nitroso compounds, or nitrones, or by the oxidation of suitable secondary amines or hydroxylamines. This method is of potential interest for industrial applications because the nitroxide precursors are cheap. However, a prerequisite for the process optimization is a thorough understanding of the underlying mechanisms.

It should be noted at this point that 2,2,6,6-tetramethyl-piperidine-*N*-oxyl (TEMPO) **57** and the related alkoxyamines, for example, **56**, can only be used for controlled polymerization of styrene and not other monomers such as acrylates. To overcome this limitation, Ciba (now part of BASF) has developed a range of proprietary cyclic nitroxides and unimolecular alkoxyamine initiators

Scheme 25 Unimolecular alkoxyamine initiator.

Scheme 26 Sterically hindered cyclic nitroxides and alkoxyamine initiators.

Scheme 27 Amphiphilic block copolymer as pigment dispersant.

that are suitable for controlled polymerization of both styrene and acrylates. Examples of these sterically highly hindered piperidine,¹⁹⁰ piperazinone,^{191–193} or diazepanone¹⁹⁴ nitroxides and alkoxyamines **58–62** are shown in Scheme 26.

The piperazinone nitroxide **60** belongs to the most effective¹⁹³ cyclic six-membered nitroxides for NMP known today and its synthesis^{191,193} is simpler than that^{195,196} of the equally effective¹⁹⁵ tetraethyl-piperidone-*N*-oxyl **63**. The industrial NMP process was reported¹⁹⁷ by Ciba in 2003. Using NMP, Ciba developed and commercialized a range of block copolymer pigment dispersants^{197–203} which offer advantages in rheology of pigment concentrates, their stability, and coloring properties. The optimal block copolymer pigment dispersant consists of (i) a B-block bearing

suitable anchoring groups (e.g., dialkylamino), which adsorb to the surface of a pigment particle; and (ii) an A-block with stabilizing groups which compatibilize the dispersant within the medium and prevent pigment agglomeration and coagulation. The design and synthesis of the amphiphilic blockcopolymer **64** by NMP using the alkoxyamine initiator **59** is exemplified in Scheme 27. The chemistry and physics of polymeric pigment dispersants have been reviewed²⁰² by Auschra and Pirrung.

In 2005, Elf Atochem (now Arkema) commercialized SG-1 (**65**), an acyclic phosphonylated α -hydrido nitroxide^{204,205} and BlocBuilder® MA²⁰⁶ (**66**), its related alkoxyamine^{206–208} which allows controlled polymerization of styrenic, acrylic, and some acrylamido monomers (Scheme 28).

Scheme 28 Acyclic and indolyl nitroxides and alkoxyamines.

Recently, Arkema reported the development²⁰⁹ of NMP-based block copolymers (Nanostrength®) consisting of PMMA surrounding a center block of poly(butyl acrylate). However, only the central poly(butyl acrylate) block is controlled. These copolymers can be used as tough thermoplastics, thermoplastic elastomers, or toughening additives for epoxy thermosets. NMP is not suitable for polymerization of nonconjugated monomers such as vinyl acetate, vinyl chloride, or *N*-vinyl pyrrolidone. Also unsolved is the controlled homopolymerization of methacrylates although promising results were reported²¹⁰ with the indolyl nitroxide **68**. However, well-controlled and living copolymerization of methyl methacrylate with only 5–10% of styrene²¹¹ or acrylonitrile²¹² or as little 1% of 9-(4-vinylbenzyl)-9-*H*-carbazole²¹³ is possible. From the industrial point of view, it is important that NMP, ATRP, and RAFT are amenable^{155, 214–220} to aqueous emulsion or mini emulsion polymerization even though some issues²²¹ remain to be solved. One issue is that NMP requires relatively high temperatures, typically in the range of 100–140 °C. Interesting attempts have been made to use nitroxide mediators in radical photopolymerization.²²²

A low-cost and upscalable synthesis of nitroxides or the related alkoxyamines is necessary to allow their use in industrial NMP. For example, the relatively expensive TEMPO **57** can be replaced by the much cheaper and industrially available 4-hydroxy-2,2,6,6-tetramethyl-piperidine-*N*-oxyl or its readily available 4-alkoxy- or 4-acyloxy derivatives for polymerization of styrene. The nitroxides **58**,^{190,194} **60**,^{191,193} and **65**^{223,224} can be prepared by simple reactions without expensive organometallic reagents, as is the case for the TIPNO²²⁵ (*N*-tert-butyl-*N*-2-methyl-1-phenylpropyl nitroxide) nitroxide **67** which is very popular in academic laboratories.

Similarly, transformation of the nitroxide into the corresponding alkoxyamine initiator (e.g., **58** to **59** or **65** to **66**) must be industrially feasible. A variety of methods for the preparation of alkoxyamines exist,^{226–229} but only a few are suitable for large-scale, multiton synthesis. The reported industrially relevant methods rely on coupling of nitroxides with C-centered radicals, which, in turn, are generated from either activated alkyl halides with Cu or Cu(I) salts²³⁰ or from hydrocarbons and *t*-butylhydroperoxide.²³¹ In most cases, the nitroxide group remains covalently attached to the NMP polymer. This is usually not a problem, but, nevertheless, possibilities²³² for its removal exist.

4.1.2 Atom-Transfer Radical Polymerization

ATRP is arguably among the most versatile CRDRP method for building complex polymer architectures with a high degree of precision. It can be run over a large range of temperatures, starting at 0 °C or below, with a broad range of monomers (with the exception of acids) using relatively easily accessible (optionally functionalized) initiators. Despite this, the method was not readily accepted by industry because of the large amounts of metallic catalysts (0.1–1 mol% vs monomer) and ligands required. Even though several methods for catalyst removal²³³ exist, they are too expensive on an industrial scale. Significant progress was made possible with the invention of activators regenerated by electron transfer (ARGET)^{181, 234–236} and initiators for continuous activator regeneration (ICAR)^{181, 237} modifications of ATRP by Matyjaszewski and coworkers. In ARGET-ATRP, an excess of reducing agent (e.g., ascorbic acid, copper(0), or tin octoate) relative to catalyst is used to continuously regenerate the Cu(I) activator species

Scheme 29 Alkyl halides and ligands for ATRP.

by reduction of Cu(II) products which are formed by unavoidable radical termination. In ICAR-ATRP polymerization, radicals are continuously generated by conventional initiators (e.g., AIBN) to reduce the Cu(II) species and thus regenerate the active Cu(I) activators. Using these techniques, the amount of Cu catalyst can be reduced²³⁸ by several orders of magnitude down to 10–50 ppm. This low amount of residual Cu catalyst may be acceptable for some applications. Use of ARGET to reduce the concentration of the Cu catalyst in solution-ATRP in batch, semibatch, and continuous reactors has been reviewed.²³⁹

A new dimension in the reduction of Cu catalyst in ATRP is represented by the single-electron-transfer-controlled radical polymerization (SET-CRP) developed by Percec *et al.*^{240–243} In this method, Cu(0) activates the polymerization and is converted by transfer of an electron to the alkyl halide (initiator or dormant chain) into a Cu(I) species. The latter rapidly disproportionates in polar solvents (H₂O, alcohols, dipolar aprotic solvents) in the presence of amine ligands into Cu(0) and the Cu(II) deactivator. The atomic Cu(0) catalyst is much more reactive than the Cu(I) species used in ATRP, so that only small amounts have to be used. SET-CRP allows rapid polymerization of both activated (acrylates, methacrylates) and nonactivated (vinyl chloride) monomers in environmentally friendly solvents at room temperature with even less catalysts than ARGET or ICAR. It is expected that these new advances will facilitate implementation of ATRP in industry, which up

to now, similarly to other CRDRP techniques, has not proceeded as fast as originally expected. Matyjaszewski at Carnegie Mellon University founded the ATRP Consortium (1996–2001) and the CRP Consortium (2001–present)²⁴⁴ with the goal to assist major industrial companies in this transfer. One success was registered by Kaneka, which commercialized^{180,187} moisture and photocurable telechelic polyacrylates prepared by ATRP for use as sealants and adhesives, or in coatings. In addition, at least two start-up companies, “ATRP Solutions,”²⁴⁵ and “Warwick Effect Polymers,”^{187,246} are fostering industrial ATRP. Finally, the availability of the ATRP reagents deserves a brief comment. Copper and Cu(I) salts as well as the typically used alkyl halides, for example, **69–71** (Scheme 29), are readily available. The situation is more complicated with the amine ligands. Only *N, N, N', N'', N''*-pentamethyl-diethylenetriamine (PMDETA) **72** is commercially available (e.g., BASF) in large quantities but not the most effective²³⁵ ligands, for example, **73–75**.

4.1.3 Degenerate-Transfer Radical Polymerization

By far the most important method of DTRP is RAFT, which is an extremely versatile tool for the synthesis of complex polymeric architectures in bulk, organic, or water solution or in dispersed media. It is compatible with the widest range of

Scheme 30 Examples of RAFT/MADIX agents.

polymerizable monomers of all CRDRP techniques. From the process point of view, a RAFT agent can simply replace the conventional chain transfer agent, requiring little or no change in established industrial setups. This broad applicability puts²⁴⁷ RAFT in the position to become a key industrial CRP method. All aspects of RAFT are covered in the “*Handbook of RAFT Polymerization*”²⁴⁸ and in recent reviews.^{209,247,249–251}

Similar to alkoxyamines in NMP, RAFT agents must be readily available. A recent overview²⁵² covers various RAFT agents and their synthesis. Scheme 30 shows examples **76–79** of typical RAFT agents. Note that RAFT using xanthates as controlling agents is called *macromolecular design by interchange of xanthates* (MADIX).²⁵³

The trithiocarbonate **78** (BlocBuilder® DB)²⁰⁶ was developed by Arkema to commercial stage, and the xanthate **79** (Rhodixan® A1) can be obtained under licence from Rhodia. However, RAFT polymers are always yellow to red in color, which is clearly not acceptable in many applications. Fortunately, a variety of methods^{251,254} are available to remove the thiocarbonylthio end group from the polymer or use it for further transformations, for example, for synthesis of block copolymers. Advances in synthesis of degradable “green” polymer materials via RAFT have been reviewed²⁵⁵ by Perrier and Semsarilar. Rhodia recently reported^{256,257} the use of MADIX for the development and commercialization of Rhodibloc® RS block copolymers for the stabilization of emulsions.

Last but not least, it should be mentioned that the first industrially applied CRP was most likely the iodine-transfer polymerization²⁵⁸ used by Daikin Industries for the preparation of fluorinated thermoplastic elastomers.¹⁸⁷

5 MAIN COMMERCIAL POLYMERS MADE BY RADICAL POLYMERIZATION

It is beyond the scope of this article to discuss the synthesis and properties of the individual polymers that are made by RP. A detailed overview appears, for example, in the “*Industrial Polymers Handbook*”¹⁷ or the book¹⁸ by Campo. The monograph²⁵⁹ of Scheirs and Priddy provides in-depth information on all aspects of styrenic polymers and copolymers. Excellent monographs^{11,12} on dispersion polymers are also available. Abundant information on PVC can be found in the “*Practical Guide to Polyvinyl Chloride*”²⁶⁰ and in the special issue (2002, vol. 27(10)) of *Progress in Polymer Science*. The technical processes of PVC production have been reviewed¹⁵⁴ by Saeki and Emura. Development of PVC from its discovery to mass production is recounted by Braun.²⁶¹ Comprehensive information on polyethylenes, including LDPE which is made by RP, is available in “*Practical Guide to Polyethylene*”²⁶² or in Ref. 121.

6 CONCLUSION

Conventional RP has reached a very high level of sophistication and is among the most important industrial polymerization techniques; about 45% of all synthetic polymers are made via this method. The most rapidly developing area of synthetic polymer chemistry today is CRP. Even though considerable progress has been made in CRP during the last two decades, only a very small part of its tremendous potential could be put into industrial practice up to now. However, the recent advances in CRP give reason to expect that new, high-valued products, rather than replacements for existing polymers, will be developed in the very near future.

Spin Labels and Spin Probes

David Bardelang, Micaël Hardy, Olivier Ouari and Paul Tordo

SREP, UMR 6264, Université de Provence/CNRS, Marseille, France

1 INTRODUCTION

Free radicals are neutral or charged compounds with an open-shell configuration resulting from an electronic structure characterized by the existence of one (monoradical) or several (polyradical) single occupied molecular orbitals. The highly reactive, often transient nature of radicals reflects the fact that their major reactivity pathways (dimerization, hydrogen abstraction, and disproportionation) are strongly favored thermodynamically and usually occur with little activation barrier. Then, most free radicals are very short-lived species rather difficult to characterize; however, some can be strongly stabilized by electronic and steric effects, making them stable, “that can be isolated and handled as pure compounds,” according to Griller and Ingold’s definition.¹ The properties exerted by the specific combination of open-shell configuration and chemical stability have been exploited to develop many applications^{2–4} involving stable radicals such as reporter molecules, chemical reagents, building blocks for new magnetic materials (see **Physical Properties of Thiazyl Radicals Toward Conductive and Magnetic Materials**), spin polarization transfer agents, and so on.

Nitroxides and to a lesser extent trityl radicals constitute the two major classes of stable radicals used as reporter molecules. Nitroxides^{2–6} are easily the most well-known class of radicals including a large number of stable structures such as the popular TEMPO **1** ($Y = H$, Figure 1) and its derivatives (see **Nitroxides in Synthetic Radical**

Chemistry). The electronic structure of nitroxides is characterized by the existence of a stabilizing π_{N-O} three-electron bond with an unpaired electron in a π^* orbital and substantial spin density on both N and O. The dimerization of nitroxides does not result in a gain of bonding electrons, and at room temperature, the formation of symmetric dimers R_2NOONR_2 has never been observed, demonstrating the inherent stability of the $R_2NO^{\bullet}$ framework.

Gomberg’s discovery of the triphenylmethyl (trityl) radical **2** (Figure 1) was a landmark discovery as it marked the beginning of organic free radical chemistry (see **The History of Free Radical Chemistry**).⁷ Under anaerobic conditions, **2** is highly persistent, this stability is ascribed largely to steric protection of the central carbon by the three phenyl groups that adopt a propellor conformation, with the rings twisted by $\sim 30^\circ$ with respect to the plane containing the central carbon and the three *ipso* carbons. Partial delocalization of the unpaired electron into the phenyl rings decreases the electronic energy, but it induces radical reactivity at the *para* carbons. Substitution of the *para* hydrogens and introduction of bulky substituents on the phenyl rings can lead to stable trityl radicals such as **3** (Figure 1).

The shape of the electron paramagnetic resonance (EPR) spectrum of a free radical depends on the motional dynamics of the radical and on various parameters (polarity, molecular oxygen concentration, pH, etc.) characterizing the free radical microenvironment. Moreover, EPR spectroscopy is

Figure 1 Structure of TEMPO **1** (Y = H), triphenylmethyl radical **2** and Ox063 **3**.

a sensitive method that allows one to get easily spatial (distance between radical centers) and temporal (tumbling rates) information (see **Analysis of Radicals by EPR**). Thus, EPR proved to be immensely useful to the characterization of complex chemical and biological systems, including free radicals as reporter molecules. Different techniques have been developed that provide a wealth of information on systems into which either covalently (spin labels) or noncovalently (spin probes) bound stable radicals have been introduced. Whatever the mode of bonding of the reporter molecule to the system under investigation, these techniques are usually named spin labeling. This field of research has undergone a tremendous development during the past 30 years and results have been gathered and discussed in different books and reviews. In the space allowed in this article, we cannot provide an exhaustive survey of each technique but rather a brief presentation of their background and recent developments involving nitroxides or trityl radicals as reporter molecules.

Although EPR is a very sensitive technique, it is very rare that the steady-state concentration of transient radicals intervening in chemical reactions reaches the EPR detection threshold. A coupled EPR/spin trapping (EPR/ST) technique has been developed to overcome this limitation. Basically, EPR/ST consists of adding a transient radical of interest to a diamagnetic spin trap, this addition giving rise to an EPR detectable spin adduct (usually a nitroxide spin adduct). A successful EPR/ST experiment not only supports strongly the formation of a transient radical in a chemical reaction but it can also provide detailed information on its chemical structure.

2 SPIN LABELING

The basic idea underlying the spin labeling approach is to tag a material (organic polymer, biological macromolecule or system, supramolecular assembly, etc.) with a specific label whose properties make it possible to collect information on the material by an appropriate physical method. Although the method could use any free radical or paramagnetic metal ion or even a group with a long-lived triplet state, at least 99% of the reported spin labeling studies employ nitroxides either as spin labels or spin probes and EPR to collect information.

2.1 Spin Labels and Spin Probes in Biological Systems and Organic Polymers

Spin labeling, introduced by H. McConnell,⁸ who coined the name, has been an accepted physical biochemical technique for over 40 years and is nowadays recognized as an important tool for the determination of structural characteristics of biological membranes and a wide range of both soluble and membrane proteins of arbitrary molecular weight.^{9–17}

Several EPR approaches can be used to detect and follow changes or dynamic interactions with either proteins, peptides, or substrates and to measure distances between two labeled sites.¹⁸ Hundreds of nitroxide spin labels or spin probes have been tailored for biological spin labeling,^{5,6,9,10,19–22} the great majority belongs to the following classes (Figure 2):

- the 2,2,6,6-tetramethyl-piperidine-*N*-oxyl nitroxides (**A**), in which the substituents are typically at C4;

Figure 2 Principal classes of nitroxides used as spin labels or spin probes.

- the 2,2,5,5-tetramethylpyrrolidine-*N*-oxyl nitroxides (**B**) and the 2,2,5,5-tetramethylpyrroline-*N*-oxyl (**C**) nitroxides in which the substituents are typically at C3;
- the 5,5-dimethyl-oxazolidine-*N*-oxyl nitroxides (**D**, doxyl), which are attached to the labeled compound at the 2 position;
- the proxyl (**E**) and azethoxyl (**F**) nitroxides;
- the imidazoline-*N*-oxyl (**G**) and imidazolidine-*N*-oxyl (**H**) nitroxides.

All these stable nitroxides bear no hydrogen atoms on the carbons attached to the nitroxyl nitrogen, that is, the α -carbons; many typical examples are depicted in figures shown herein.

2.1.1 Spin Probes for the Study of Biological Membranes

Since the very beginning of the development of spin labeling, numerous studies have been devoted to study biophysical properties of biological membranes.^{16,23–30} These include structural and dynamic parameters,^{23–26} protein–lipid interactions,^{16,27–29} polarity and proticity,^{28,30} penetration depths of metal ions, and so on.²⁸ The main spin probes used for these studies are shown in Figure 3, the *n*-DSA and *n*-PCSL probes provide a number of unique approaches for determining several membrane properties as a function of bilayer depth. The orientation-dependent behavior of various nitroxide spin labels incorporated into aligned membrane systems has also been investigated.^{31–34}

2.1.2 Spin Labels for the Study of Proteins

A few of the nitroxide spin labels developed^{35–48} to investigate the structure and dynamics of proteins are shown in Figure 4. They can be covalently attached to proteins through various functional groups,³⁷ the amino acid residue that is labeled varies with both the label and the protein but typical targets include cysteine, serine, and lysine. Spin-labeled unnatural amino acids such as the 2,2,6,6-tetramethyl-piperidine-1-oxy-4-amino-4-carboxylic acid (TOAC), **27**,^{38–43} **28** (β -TOAC),^{44,45} or **29** (POAC)⁴⁶ and **30**⁴⁷ were developed as a means for spin labeling the backbone of peptides.

In the late 1980s, thanks to the design of **26** (MTSL)⁴⁸ and the outstanding work of Hubbell and coworkers,^{49–51} who recognized that site-directed mutagenesis makes it possible to obtain specific attachment sites for spin labels at any desired position in a protein, a major breakthrough occurred with the development of site-directed spin labeling (SDSL). MTSL is a sulfhydryl-specific spin label that reacts specifically with the accessible cysteine residues of a protein.⁴⁸ SDSL utilizes site-directed mutagenesis to replace the residue of interest with a cysteine and all reactive native cysteine residues with a suitable substitute. The unique cysteine residue of the recombinant protein is then specifically reacted with MTSL (Figure 5a) to generate a nitroxide side chain sensitive to the local environment. Since its finding SDSL has been widely used for *in vitro* studies on both soluble and membrane proteins, and the topic has been regularly reviewed.^{12–14,16,17,52–54} Among the impressive amount of pertinent results obtained using SDSL, those concerning information on structural aspects of bacteriorhodopsin^{51,55–68} illustrate particularly well the very high potential of the SDSL technique.

SDSL can be challenging for proteins that contain functionally important native cysteine residues or disulfide bonds. To make SDSL amenable to any protein, an orthogonal labeling strategy, that is, one that does not rely on any of the functional groups found in the common 20 amino acids, was developed. In this approach, a genetically encoded unnatural amino acid is reacted chemoselectively with an especially designed spin label.⁶⁹ For example, the genetically encoded unnatural amino acid *p*-acetyl-L-phenylalanine is

Figure 3 Main spin probes used to investigate biological membranes.

Figure 4 Main spin labels used to investigate proteins.

Figure 5 (a) Labeling of a cysteine residue with MTSL. (b) Orthogonal labeling of *p*-acetyl-L-phenylalanine, a genetically encoded unnatural amino acid.

reacted with **32** to generate a ketoxime-linked spin label (Figure 5b). Other nitroxides designed for orthogonal SDSL, such as **31**, have been prepared.⁷⁰

2.1.3 Spin Labels for the Study of DNA and RNA Molecules

Spin labeling of nucleic acids has been used since the early 1970s to get structural and dynamic

Figure 6 Examples of nitroxides used to spin label DNA and RNA molecules.

Figure 7 Biochemistry of the 5' ps labeling scheme according to Grant and Qin.⁸⁴

information on RNA/DNA architectures under biological conditions, and the early works have been reviewed by Bobst⁷¹ and Keyes and Bobst.⁷² Over the past decade, several strategies have been established to site-specifically spin label oligonucleotides.⁷³ Some nitroxide spin labels tailored for this purpose are shown in Figure 6. Strategies were developed to attach nitroxides at specific backbone,^{74–76} sugar,^{77,78} and base^{79–82} positions. Methods have also been reported for attaching nitroxides at the 5'-terminus of RNA and DNA molecules.^{83,84} For example, Grant and Qin⁸⁴ developed the 5' ps labeling scheme that utilizes T4 polynucleotide kinase to transfer the γ -phosphorothioate group of adenosine-5'-O-(3-thiotriphosphate) (ATP γ S) to the 5'-terminus of DNA or RNA molecules (Figure 7).

Spin labeling of DNA molecules^{85–87} can also be performed using the highly chemoselective azide-alkyne “click” reaction.⁸⁸ For example, after its automated synthesis, an oligonucleotide incorporating modified nucleobases bearing ethynyl side chains can be spin labeled (Figure 8), with nitroxides bearing an azido function.⁸⁹

Noncovalent SDSL of nucleic acids has been introduced by Shelke and Sigurdsson,⁹⁰ using nitroxide **48** (Figure 6). Nitroxide **48** is an analog of cytidine, with a nitroxide-bearing isoindol moiety fused to cytosine by an oxazine linkage, and forms a stable base pair with guanine (Figure 6).

2.1.4 Distance Measurements in the Nanometer Range (1.5–8 nm)

Distance of 1.5–8 nm between two spin labels can be measured in macromolecules and supramolecular assemblies by pulse EPR techniques,⁹¹ namely pulse electron double resonance (PELDOR) or double quantum coherence.⁹² PELDOR is frequently used during SDSL structure determination of biomacromolecules,^{14,17,81,93–95} it has also been used to investigate the structure of organic polymers. Various new spin labels and model spin labels (Figure 9) have been prepared to optimize and test the reliability of distance measurements by the PELDOR approach.^{96–102} Using nitroxides **49–53** as models, Schiemann and coworkers⁹⁷ showed that a single PELDOR data set yields not only distances and thereby precise geometric information on the nanometer scale but also the number of spins n in a molecule.

Godt and coworkers⁹⁸ developed nitroxides **54** as conformationally unambiguous spin labels. Spin labels **54** can be attached through cross-coupling to the macromolecules of interest and provide access to data that are unbiased by conformational flexibility within the spin label.¹⁰² The spin label **56** exhibits slow enough spin-echo dephasing to permit accurate distance measurements at temperature up to 125 K in 1 : 1 water/glycerol.¹⁰¹

Figure 8 Use of click-chemistry to spin label RNA or DNA molecules.

2.1.5 Spin Labels and Spin Probes for the Study of Organic Polymers

Spin labeling has been used to address various structural problems of organic polymers. The implemented techniques, spin labels, and spin probes are almost identical to those presented above and only some books and reviews are mentioned herein.^{102–111}

2.1.6 Spin Probes for Imaging Techniques (MRI, EPRI, PEDRI, DNP)

Nitroxides as MRI Contrast Agents

Nitroxides have unpaired electrons that confer them the ability to enhance image contrast in

magnetic resonance imaging (MRI) via a proton T_1 -shortening effect, similar to the one observed for the well-known gadolinium-based contrast agents. Nitroxides were evaluated as potential contrast agents in MRI in the mid-1980s, and due to their slower reduction rate in biological systems, 3-carbamoylPROXYL (**153**, Figure 21) and 3-carboxyPROXYL (**134**, Figure 17) were the most used and studied nitroxide contrast agents.¹¹² However, due to their low relaxivity ($0.15\text{--}0.20\text{ mM}^{-1}\text{ s}^{-1}$ at 25°C and 1.5 T for mononitroxides) compared to gadolinium complexes ($2.5\text{--}5.5\text{ mM}^{-1}\text{ s}^{-1}$ at 25°C and 1.5 T for monomeric Gd(III) complexes) and their rapid bioreduction to the corresponding diamagnetic hydroxylamines, nitroxides were classified as nonoptimal compared to the metal-based contrast agents.^{113–117}

Figure 9 Model spin labels used to optimize and test the reliability of distance measurements by the PELDOR approach.

Nevertheless, because of their easy conjugation to biomolecules or particles, allowing tissue or articular targeting,^{118,119} the potential blood–brain barrier permeability of some nitroxides,¹²⁰ and their low toxicity,¹²¹ nitroxides have proved to be useful for specific applications.

The effect of combining several nitroxides (up to three) on relaxivity in a molecule was studied and a good linear relation between the T_1 —contrast enhancement and the concentration of nitroxide groups was found.¹²² Several nitroxide-labeled dendrimers were described in the past two decades and it was shown that dendritic polynitroxides exhibited higher relaxivity per nitroxide compared to monomeric nitroxide, this enhancement being attributed to an increase in the rotational correlation time.^{118,123–125} Recently, hyperbranched polymers carrying 20 TEMPO units have been prepared by postfunctionalization, which exhibited high relaxivity improvement with regard to monomeric TEMPO.¹²⁶

Spin Probes for EPRI and PEDRI

With the recent developments and technological advances in low-field EPR imaging (EPRI), nitroxides and trityl radicals have shown to be promising candidates for imaging applications.¹²⁷ EPRI is unique for free radical imaging and is a very sensitive technique. However, its applications to living organisms are limited by different characteristics (half-life time in biological milieu, linewidth, and distribution) of the spin probes. To overcome these limitations, strategies have been developed based on

- the use of free radicals with improved resistance to bioreduction,¹²⁸
- the use of trityl radicals^{129,130} and isotopically labeled nitroxides^{131,132} exhibiting narrow linewidths,
- the selective delivery of nitroxide probes^{133,134} (Figure 10).

Proton electron double resonance imaging (PEDRI, also named Overhauser-enhanced magnetic resonance imaging, OMRI) has shown to be

Figure 10 Spin probes for imaging applications.

a promising alternative due to the combination of sensibility to high resolution.^{135–140} In PEDRI experiments, an EPR resonance of the free radicals is irradiated during the acquisition of a magnetic resonance image. The polarization transfer from electron spins to the proton spins results in the enhancement of the nuclear magnetic resonance (NMR) signal in regions of the sample containing the free radical probes, bringing information on its spatial distribution in the final image. As observed for EPRI, isotopically labeled nitroxides and bioreduction resistant nitroxides are promising candidates for PEDRI (Figure 10).

Spin Probes for DNP

The development of dynamic nuclear polarization (DNP) technique associated to NMR and MRI has witnessed a large interest in the past decade and new free radicals and dinitroxides have been designed and studied as polarizing agents.^{141–143} In a typical DNP experiment, the larger polarization of the electron spin system is transferred onto the nuclear spin

system by microwave irradiation of EPR transitions. Hyperpolarization provides a means to increase the nuclear polarization by several orders of magnitude (up to 100 000) from the Boltzmann polarization. The maximum theoretical enhancement achievable is given by the gyromagnetic ratio (γ_S/γ_I), being ~ 660 for ^1H nuclei and ~ 2600 for ^{13}C nuclei. DNP is the extension of the original Overhauser effect and its applications to high fields proved to be challenging till high-power high-frequency microwave sources were made available and the theory better understood. DNP technique rapidly appeared as a breakthrough in NMR/MRI, notably for the studies on protein structures¹⁴⁴ and for real-time metabolic imaging.¹⁴⁵

At high magnetic field (5 T) in the solid state (90 K) and pumping at 140-GHz microwave frequency, Griffin reported that using TEMPO-based biradicals as polarizing agents improved polarization compared to monoradical TEMPO.^{146,147} Thus, the highest enhancements so far measured were obtained using TOTAPOL¹⁴⁸ **61** and bTbK¹⁴⁹ **62**

Figure 11 Nitroxides as polarizing agents for DNP applications.

Figure 12 Reversible protonation of imidazoline and imidazolidine-type nitroxides (IMSTSL, **112**, $A_N = 1,575$ mT, **112-H⁺**, $A_N = 1.434$ mT, $\Delta A_{\text{iso}} = 0.141$ mT).

dinitroxides, with enhancement values of 230 and 325, respectively (Figure 11).

Recently, Prisner and coworkers demonstrated that DNP is possible also in liquids at high magnetic fields (400-MHz NMR frequency and 260-GHz microwave source) using Fremy's salt **63**.¹⁵⁰ Ardenkjaer-Larsen *et al.*¹⁵¹ were involved early in the design of polarizer for the generation of hyperpolarized spin systems in the solid state at very low temperatures (2–5 K) followed by a rapid dissolution process and sample transfer to the NMR/MRI apparatus. This approach has gained a tremendous interest in the MRI field allowing real-time metabolic studies, and trityl radicals such as Ox063 **3** (Figure 1) have been largely used as polarizing agents in such systems.

It has been reported that using ^2H and ^{15}N isotope-labeled TEMPONE (**132**, Figure 17), the effective saturation factor can be increased¹⁵² in ^1H -DNP experiments (water solution and pumping at 9.7-GHz microwave frequency in a 0.34-T NMR field).

2.1.7 Spin Probes for pH Measurements

Nitroxides as pH-Sensitive Spin Probes

Proton concentration measured as pH is of fundamental importance in the biochemistry of living systems and pH changes have been associated with many physiological and pathological processes. Thus, *in vitro* and *in vivo* measurements of pH in noninvasive way could provide useful information about clinical diagnostic applications. EPR has been shown to be an appropriate technique to perform such measurements, the principle is based on the monitoring of EPR parameters (A_N and g factor) of nitroxides bearing functional groups, adjacent to the nitroxyl function, that can be reversibly protonated (Figure 12).

Imidazoline as well as imidazolidine-type nitroxides containing a nitrogen at position 3 of the heterocycle are considered to be the most suitable for pH-sensitive spin probes due to the high sensitivity of their EPR parameters to pH changes.

Keana *et al.*¹⁵³ and Volodarsky and coworkers¹⁵⁴ first reported the pH dependence of the EPR spectra of imidazolidine-type nitroxides. Khramtsov *et al.* and Weiner *et al.* considered the conditions for fast and slow exchange between unprotonated and

protonated forms of nitroxides, they showed that at X-band, the slow exchange condition is $3 < \text{p}K_a < 11$.^{155–157} They also showed for the intermediate pH values that at X-Band, only the high-field line of the EPR spectrum splits into two lines whose intensities changed reversibly with pH (Figure 13c). Using higher frequencies (35.5 GHz, Q-Band and 140 GHz, G-band), all the lines of the nitrogen triplet were split, proving that the use of higher frequencies improves the precision in g -factor determination, making this parameter a good alternative to ΔA_{iso} measurements *in vitro* (Figure 13a and b).^{158,159} However, the use of high-frequency EPR is limited for *in vivo* experiments.

Further works on the imidazoline ring have shown that, depending on substitution at position 4, the $\text{p}K_a$ of the molecules can vary from 1 to 12.5. During the past decades, a large number of pH-sensitive nitroxides have been synthesized with

- different ranges of pH sensitivity (**64–72**, **76–87**, and **91–96**),^{160–163}
- different degree of lipophilicity (**82–87**, **97–111**, and **118–121**),^{160, 164–166}
- different stability toward bioreduction (**73–75**, **88**, **113**, and **122**),^{167–171}
- different functional groups (**89–90**, **112**, and **114–117**).^{172–176}

Chemical structure, $\text{p}K_a$ values, and ΔA_{iso} for some of these nitroxides are listed in Tables 1 and 2.

As an illustration, a few applications of pH-sensitive spin probes to biological system are described herein, further information can be found in review articles published recently.^{156,157,176}

Ptushenko *et al.*¹⁷⁷ measured intrathylakoid pH in chloroplast suspension using nitroxides **64–67**, **71**, and **77** (Table 1). Tikhonov *et al.*¹⁷⁸ used **64–67** to measure the light-induced change in the intrathylakoid pH in isolated bean chloroplasts.

Potapenko *et al.*¹⁶⁸ studied the localization and monitored the acidity in the rat stomach using imidazoline-based nitroxide **88**. The combination of bulky groups at the α -position of the nitroxyl group to enhance the stability toward bioreductant agents and the two ionizable groups to extend the range of pH sensitivity make **88** a good candidate for pH measurements in the rat stomach. Using PEDRI, the authors monitored the distribution of **88**. The use of longitudinally detected EPR (LODEPR), and field-cycled dynamic nuclear

Figure 13 The EPR spectra of an aqueous solution of HMI **64** at $\text{pH} \sim \text{p}K_a$ performed at different microwave frequencies. [With kind permission from Springer Science+Business Media: Appl. Magn. Reson., Stable nitroxyl radicals as pH, thiol and electron transfer probes, 31, 2007, 357, L. M. Weiner.]

polarization (FC-DNP) techniques was to follow the drug-induced perturbation of acidity in the stomach. Previously, the same authors studied the successful use of low-field EPR-based techniques to detect **64** in the rat stomach.¹⁷⁹

Also, **112** derivatives were used as pH-sensitive nitroxides to determine interfacial $\text{p}K_a$ and local electrostatic field in phospholipid membranes and micellar solutions.^{159,180}

Further applications have illustrated the usefulness of these pH-sensitive nitroxide probes in different systems such as in liposomes,¹⁷⁵ in drug release tablets,¹⁸¹ and in gold nanoparticles.¹⁸²

Recently, a self-assembled amphiphilic copolymer (PEG-*b*-PS-aminoTEMPO) was designed and evaluated as a pH-sensitive probe (Figure 14).¹⁸³

Trityl Radicals as pH-Sensitive Spin Probes

Water-soluble triarylmethyl (TAM) radicals are also used for pH measurements, thanks to their higher stability compared to nitroxides in living tissues,¹⁸⁴ their narrow single EPR line width, and their pH-sensitive magnetic resonance parameters.

The study of the pH dependence of the EPR spectra of Ox063 **3**, cTAM₀ **123**, cTAM₁ **124**, and cTAM₂ **125** were performed by Bobko *et al.*¹⁸⁵ (Figure 15). The authors showed that the additional A_H coupling constant of cTAM derivatives facilitates the pH measurement at low frequencies allowing *in vivo* experiments. However, the low $\text{p}K_a$ of the above TAM derivatives limited the experiments at physiological pH. In order to overcome this problem, the incorporation of ionizable groups such as amino groups was developed by Dhimitruka *et al.*¹⁸⁶ and allowed the pH measurement in a range of pH from 6.8 to 9.0 using aTAM_{1–5} (**126–130**, Figure 15).

TAM derivatives bearing a dendritic moiety were prepared and tested as pH spin probes by Liu *et al.*¹⁸⁷ They showed the highest sensitivity and stability of these probes in acidic conditions and in the presence of reactive oxygen species (ROS) compared to CT03 **137** (Figure 19). Moreover, in acidic media, **131** (Figure 15) did not show self-aggregation. The acid-induced release of Cu^{2+}

2.1.8 Spin Probes for Oximetry

Nitroxides as Oximetric Spin Probes

Molecular oxygen plays a crucial role in cellular metabolism and abnormal tissue oxygenation is involved in a number of diseases (cancer, ischemic diseases, etc.).²⁵ As a result, the measurement of oxygen concentration *in vitro* and *in vivo* is fundamental to study many physiological and pathological processes. There are different oxygen measurement techniques and among them, spin probes coupled to EPR (EPR oximetry) is a noninvasive technique widely used in biological systems. The principle is based on the interaction of molecular oxygen and the paramagnetic spin probes (Heisenberg exchange). This interaction has shown to be sensitive and reliable to allow the quantification of the oxygen concentration in various systems (Figure 16).

The two main types of spin probes used in EPR oximetry are soluble spin probes¹⁸⁸ and stable paramagnetic particles (lithium phthalocyanine (LiPc),¹⁸⁹ charcoals,^{190,191} India ink,¹⁹² etc.). In this brief report, we will focus on the development and use of soluble nitroxide and trityl radical spin probes. The specifications for a useful oximetric spin probe are a narrow line shape EPR signal, oxygen sensitivity, stability, solubility, and low toxicity.

Nitroxides (Figure 17)^{193,194} were first used as spin probes for oximetry, to increase their sensitivity to O_2 concentration, various deuterated nitroxides derived from **133** and **132** were prepared and used for *in vivo* applications.^{121, 195–197} Nitroxide **136** (Figure 18) exhibits a six line EPR spectrum with very narrow lines due to the coupling with nitrogen and the hydrogen attached to C4 (0.05 mT). Analysis of the broadening of the doublet lines allowed oxygen concentration measurements in tissues and animals.^{195,198,199} More recently, Burks *et al.*¹³¹ synthesized the fully isotopically labeled (^2H , ^{15}N) nitroxide **59**, which was designed for oxygen mapping of tumor using EPRI.

Trityl Radicals as Oximetric Spin Probes

Applications of nitroxides in oximetry are limited by their sensitivity to bioreduction and the large EPR linewidth of their EPR spectra. Researchers from Nycomed Innovation's company developed TAM derivatives and showed that their stability *in vivo*

and the shape of their EPR signals make them very interesting as oximetric probes for biomedical applications.²⁰⁰ CT-03 **137**, perdeuterated CT-03 **138** (Figure 19), and Ox063 **3** show very narrow EPR linewidths and are less sensitive to bioreduction than nitroxides. Moreover, the broadening of

Figure 17 Structure of some nitroxides used as oximetric spin probes.

EPR lines due to oxygen is almost the same for trityl radicals and nitroxides (45 mT mM^{-1} of O_2); however, in oxygen-free medium, the broadening due to spin exchange is about 10 times lower for trityl radicals (1 mT mM^{-1}) than for nitroxides.^{157,184,201} These properties make TAM radicals spin probes of choice for oximetric applications.

Efforts have been made to synthesize new halogenated TAMs, taking advantage of the higher oxygen solubility in lipophilic environments compared to water. TAMs bearing fluorinated side chains (F15T-03 **139** and F45T-03 **140**, Figure 19) and possessing a high affinity for fluoruous media were prepared and used to follow subtle changes in oxygen concentration after induced ischemia in rodents.^{202,203}

PTM-TE **141** (Figure 19), a perchloro TAM, used by Dang *et al.*²⁰⁴ has proven to be highly sensitive to dissolved oxygen. *In vivo* oximetry and imaging of oxygen concentration in fibrosarcoma (RIF-1) tumor transplanted into C3H mice were performed using **141** dissolved in hexafluorobenzene as injectable probe.²⁰⁵

To improve sensitivity to oxygen concentration and intracellular permeability, Liu *et al.*²⁰⁶ synthesized various esterified trityl radicals. Among them, BT-03 **142** showed the highest sensitivity to molecular oxygen (linewidth = 0.0102 mT), whereas AMT-02 **143** and AMT-03 **144** (linewidth = 0.0203 and 0.0171 mT , respectively) showed interesting potential as intracellular probes. Experiments performed in bovine aortic endothelial cells showed the uptake of **143** by cells and its hydrolysis to **137**. Measurements of intracellular oxygen have been performed using these esterified trityl radicals.²⁰⁷

Taking into account that the presence of *para*-hydrogen on aromatic rings of TAMs limits their stability,²⁰⁸ Bobko *et al.*²⁰¹ prepared TAM-H **145** (Figure 19) containing one aldehyde and two carboxylic groups. EPR spectrum of **145** exhibits a doublet resulting from the coupling with the aldehydic hydrogen and a linewidth of 0.0105 mT in anoxic conditions. Experiments using **145** and Ox063 for oxygen consumption in Met-1 cancer cells demonstrated that **145** allowed EPR measurements at very low oxygen concentration (1 mm Hg), whereas Ox063 **3** is almost insensitive to oxygen pressures lower than 20 mm Hg (Figure 20).

More recently, Dhimitruka *et al.*²⁰⁹ described the synthesis and characterization of deuterated derivatives of Finland trityl radicals (cTAM* **146**, cTAMe* **148**, aTAM* **150**, and aTAMe* **152**) and evaluated their sensitivity to oxygen concentration. Additionally, Finland trityl radicals substituted with linkers suitable for further derivatization have been synthesized.²⁰⁹

2.1.9 Spin Probes for Redox Status Determination

Nitroxides and Trityl Radicals

The study of the biochemical profile variation is an important tool for biomedical diagnosis and for the evaluation of tissue activity. One of the biochemical profiles attracting a large interest is the redox status of cells since cellular energy production is linked to a series of oxidation reactions. Endogenous redox species, such as glutathione (GSH), ascorbate anion, thioredoxins, and NAD(P)H contribute to the overall redox control of cells. These redox species are responsive to parameters characteristic of a change in cell activity, such as oxygenation status, blood flow, oxidative stress, and mitochondrial dysfunction and altogether provide a good indication of the redox activity. Interestingly, in biological systems, nitroxide spin probes react with these

redox species to yield EPR-silent hydroxylamines as illustrated in Figure 21.

In most biological systems, one-electron reduction of the nitroxides predominates and the equilibrium is shifted toward the corresponding hydroxylamines (Figure 21) after a 10th of a minute. This feature has limited in many cases the applications of nitroxides as imaging agents in biological systems; however, monitoring the decay rate of nitroxide spin probes can provide information on the redox capacity of tissues.

Conventional EPR as well as NMR and EPRI techniques have been used in the past decade to monitor the changes in the reduction rate of spin probes in various tissues that may display different redox status.^{128,140,210–220} In the late 1990s, Kuppusamy *et al.*²²¹ measured the nitroxide reduction profiles in RIF-1 tumor-bearing mice by *in vivo* EPR spectroscopy and showed that

Figure 19 Oximetric soluble trityl spin probes.

tumor tissues were hypoxic and highly reducing when compared with normal tissues. In 2002, the same team reported the noninvasive measurements and spatial mapping of tumor redox status in tumor-bearing mice using **153** (Figure 21) as spin probe, low-frequency (1.3 GHz) spectroscopy, and (L-band EPRI) imaging techniques.²²² On the basis of their results, the authors highlighted the dominant role of GSH in the redox status of cells and the existence of heterogeneity of redox status in tumor tissue compared with normal tissue.

The influence of the nitroxide structure (Figure 22) on the reduction rate was also investigated using two cell-permeable nitroxides, **156** and **153**, and a cell-impermeable nitroxide **134**.²²³

The pharmacokinetic distribution of these spin probes was evaluated by MRI in normal tissue, tumor, kidney, and arteries in mice (Table 3). From these studies, the authors concluded that the differential reduction of cell-permeable nitroxides in normal tissue and tumor is due to intracellular processes and thus offer a noninvasive means

Figure 20 EPR spectra of aqueous solutions of (a) 100 μM Ox063 **3** and (b) 50 μM TAM-H **145** radicals measured at 37 $^{\circ}\text{C}$ and various oxygen concentrations. to monitor redox status in various tissues using T_1 -weighted MRI.

PEDRI has been used at 0.02 T to assess the ability to image the *in vivo* distribution and redox-dependent clearance of nitroxide probes in different organs of a mice.¹³⁹ In this work, the best enhancement (-7) was observed in living mouse using **134**.

Figure 21 Redox status spin reporter.

More recently, the relation of the redox status to the partial pressure of oxygen in a tumor model was studied by EPRI using **155** and LiPc microcrystals implanted in the tumor.²²⁴

A series of trityl-nitroxide biradicals were developed as spin probes for the potential simultaneous measurement of redox status and oxygenation.^{225,226}

Thiol-Specific Nitroxide Labels for GSH Detection/Quantification

Important as actors of protein-mediated signaling pathways and as critical antioxidants, thiols and notably GSH are important regulators of the redox status in cells.²²⁷ The concentration of GSH is an important indication of many physio- and pathological situations, and since many years, methods and assays have been developed to monitor and determine the GSH concentration in tissues. An EPR method based on specific labeling of thiols was proposed using thiol-specific paramagnetic reagents as shown in Figure 23.^{156,213}

The first developed spin labels were mononitroxides in the early 1960s^{228,229}; however, limitations arose rapidly due to the small difference in the EPR parameters between the labeled and unlabeled thiols. Thus, the labeling methods required an additional purification step and *in vivo* applications were hampered.

Disulfide nitroxide biradicals such as **160** (Figure 23) exhibiting intramolecular spin exchange interactions were then developed to overcome these limitations.^{230,231} The reaction of the biradical label with a thiol such as GSH is accompanied by an EPR spectral change. Using disulfide nitroxide biradicals, the GSH concentrations were determined *in vivo* in cisplatin-resistant and cisplatin-sensitive tumors.²³²

Besides thiol-specific spin probes, a large series of reactive functional nitroxides have been developed for specific labeling applications and some of them are commercially available (Figure 24).

2.1.10 Profluorescent Spin Probes

Nitroxides and to a lesser extent trityl radicals are routinely used as spin labels or spin probes for the EPR investigation of biological systems. However, in living systems such as cell cultures, tissues, and small animals, these spin labels and spin probes can react with various endogenous

biocomponents to form EPR-silent diamagnetic products.^{233–235} Nowadays, the loss of EPR signals and the low spatial resolution of EPRI techniques are the main limitations in the use of spin labels and spin probes to the EPR investigation of living systems. During the past two decades, a complementary approach using a spin probe (or a spin label) covalently linked to a fluorophore

Figure 24 Structures of some reactive nitroxide spin labels.

moiety has been developed.^{236–238} This approach is based on the efficient quenching of fluorescence emission by the close free radical center. The hydroxylamine/nitroxide redox pair acts as an on/off switch of the fluorescence. The fluorescence quenching results from an enhanced intersystem crossing of the fluorophore excited singlet state to its triplet state through electron exchange interactions with the free radical centers.²³⁹

The hybrid probe can thus report at the same time on the redox status and the presence of free radicals in the studied system. On the basis of the distance dependence of the fluorescence quenching efficiency, approaches using a nitroxide and a fluorescent probe noncovalently linked have also been used to study dynamic and aggregating systems.

Nitroxides have been successfully used for the detection of carbon-centered and peroxy radicals by high performance liquid chromatography (HPLC) via a postderivatization step of the resulting alkoxyamine adducts with fluorescamine. The technique has shown to be highly sensitive and versatile but limited to simple systems.^{240–242}

For the study of more complex systems, including enzymatic systems, aggregates, and cell cultures, a more direct strategy was developed by combining a fluorescent moiety linked to a nitroxide to prepare prefluorescent probes (Figure 25). The reduction or trapping of a radical by the nitroxide group restores the fluorescent properties of the hybrid probes, allowing characterization, quantitative evaluation, and kinetic studies.^{240, 243–251}

For instance, this strategy has also been used for the evaluation of the local reactivity of phenol antioxidants in micellar systems,²⁵² for the mapping of radicals photogenerated through a mask in polymer films,²⁵³ for imaging the thermo-oxidative

Figure 25 Profluorescent nitroxide spin probe.

degradation of polypropylene,²⁵⁴ for the quantitative analysis of vitamin C in fruit juices,²⁵⁵ for the *in vivo* detection of singlet oxygen production during photoinhibition of photosynthesis,²⁵⁶ and for probing ROS production and the redox status of cells.²⁵⁷

Perchlorotrityl radicals conjugated to a fluorophore moiety were developed as probes of superoxide radical, the spin probe exhibiting an enhancement of the fluorescence emission in the presence of KO₂ in DMSO (Figure 26).²⁵⁸

The reversible fluorescence quenching of quantum dots by nitroxides bearing ligand groups has been studied by EPR and fluorescence techniques.^{259–261} A detailed study on the quenching of terbium emission in the sensitized complex Tb(III)-carbostyryl-DTPA by TEMPOL **156** in aqueous solution has been reported.²⁶²

Figure 26 Profluorescent trityl spin probe.

Figure 27 Prefluorescent nitroxide probe base paired to guanine in DNA.

Using both the EPR spin labeling and fluorescence (after nitroxide reduction) techniques,^{263,264} the folding of the DNA cocaine aptamer was studied by incorporating a prefluorescent nitroxide probe (Figure 27) in the aptamer chain.²⁶⁵ This probe has also been used to report the identity of its base-pairing partner in duplex DNA due to the different fluorescence signals observed for the different base pairs.²⁶⁶

The intramolecular fluorescence quenching of 5-carboxytetramethylrhodamine by TEMPO both linked at various positions on a DNA strand was studied in order to evaluate a method to measure short distance changes within single molecules.²⁶⁷ This approach was used earlier to study the binding of hirudin analogs to thrombin.²⁶⁸

In membrane and lipid raft studies, TEMPO nitroxide has been used as quenching molecule of a fluorescent group incorporated into lipid bilayers to detect the presence of coexisting ordered and disordered state lipid domains in model membranes.²⁶⁹ This approach was developed earlier to study the immersion of fluorophores in membranes.^{270,271}

Structural studies and aggregation processes of biomacromolecules, including proteins, RNA, and DNA, have been largely performed by analyzing

the fluorescence quenching of chromophores by nitroxide spin probes and spin labels.^{272–275}

2.2 Spin Labels and Spin Probes in Supramolecular Systems

Since the award of the Nobel Prize in chemistry in 1987 to Cram, Lehn, and Pedersen for the development and use of molecules with structure-specific interactions of high selectivity, supramolecular chemistry, often defined as the *chemistry beyond the molecule*, has never ceased to expand its frontiers, its scope, and the field of its applications. Approximately at the same time, some scientists started to explore the interface between free radicals and macrocycles often containing cavities amenable for guest inclusion (Figure 28). In this context, the use of EPR spectroscopy proved to be immensely useful to the characterization of the paramagnetic supramolecular systems (see **Analysis of Radicals by EPR**).

The first systems to have been investigated are probably micelles, crown-ethers, and cyclodextrins. Recently, more sophisticated systems, including cucurbiturils, self-assembled cages (metal-organic polyhedra—MOPs), or self-assembling free radicals, appeared in which the degree of prediction of the arrangement of free radicals by means of the assembling building blocks raised to unprecedented levels. We can notice that after a period of time where most chemists focused on the inclusion properties of well-known macrocycles as cyclodextrins or calixarenes, the “design concept” started to be a very important component of the systems investigated. The “design concept” comes within the scope that asks for predetermined properties to be reached experimentally by a very careful determination of the structural building blocks *and* supramolecular

Figure 28 Different situations depicting the general and more peculiar role that can play radicals in systems involving molecular recognition.

Figure 29 The two approaches involving nitroxides to investigate dendrimers and their supramolecular interactions with other large objects.

interactions mediating their assemblies into systems of higher complexity. Our aim is to present the most important aspects of the developing interface between free radicals and supramolecular chemistry/concepts. As will be seen, nitroxides hold a great part of the discussion, likely due to their stability and easiness of functionalization.²⁷⁶ Since this expanding topic has recently been the object of many book chapters,^{277–279} we will focus on the main results in the context of spin probes and assembled radicals. We have to mention that trityl radicals hold a special part of radical solid-state supramolecular chemistry/recognition^{280–282} with crystalline materials that can combine porosity with interesting magnetic and molecular recognition properties. Finally, micelles, vesicles, liposomes, surfactants, and some polymers can also be considered as supramolecular systems based on amphiphile molecules self-assembling in water and creating local hydrophobic pockets amenable to lipophilic guest inclusion according to the hydrophobic effect. A large part of the scientific literature is dedicated to the study on these systems by the spin probe-EPR technique and has recently been reviewed.^{283–292}

2.2.1 Nitroxides and Dendrimers

Dendrimers are generally prepared by a bottom-up approach and are covalent, most often spherical, sea-urchin-shaped architectures. Concerning

spin probes, two approaches have been considered (Figure 29). The first that benefits from the small size of nitroxides to explore the dynamic cavities inside dendrimers (noncovalent approach) and the second that consists of branching several nitroxides on the surface of a presynthesized dendrimer to investigate its recognition properties toward a large variety of other quite large covalent assemblies.

Smith and coworkers²⁹³ reported the binding of 4-amino-TEMPO **40** to the carboxylic acid function at the focal point of a dendrimer, whereas the groups of Ottaviani and coworkers used nitroxide probes CAT-1 **169** and CAT-12 **174** (Figure 30) to explore the interior and exterior of Gd(III)-containing dendrimers that are believed to be promising candidates as contrast agents for MRI.²⁹⁴ Recently, Sueishi *et al.*²⁹⁵ reported the formation of inclusion complexes of TEMPO **1**, DTBN **170**, and 16-DSA **7** with cyclotriphosphazene-phenoxymethyl-(methylhydrazono) dendrimer G 4.5 (PMMH, **167**, Figure 30). In 1996, the surfactant spin probe CAT-16 **175** was used to explore this interface with starburst dendrimers.²⁹⁶ It was concluded that for low-generation dendrimers, they are the guests with the micelle forming CAT-16 **175** acting as a host, whereas for higher generation ones, the nitroxide is the guest and the bigger dendrimer now plays the role of the host. The same team also reported the use of ruthenium(II) phenanthroline complexes labeled with a nitroxide (**176** and **177**) to investigate the binding of the complexes on the surface of starburst

Figure 31 Covalently and noncovalently bound nitroxides with crown-ethers, polyazamacrocycles, and cryptands for the monitoring of cation recognition by EPR spectroscopy.

dendrimers.²⁹⁷ One year later, they studied the partitioning of spin probes C12T **171**, CAT-9 **173**, and CAT-16 **175** between the surface of dendrimers and micelles and they also could gain information about the interaction between these

two self-assembled and molecularly assembled systems.²⁹⁸

Janssen and coworkers²⁹⁹ later followed by Singel and coworkers studied the distribution of nitroxides on the surface of dendrimers.³⁰⁰ On the

other hand, the research group of Ottaviani have been very active in this field³⁰¹ and especially according to the second approach, they studied the interactions of spin-labeled dendrimers with (i) other dendrimers,³⁰² (ii) vesicles,^{303,304} (iii) polynucleotides,³⁰⁵ (iv) DNA,³⁰⁶ (v) porous materials,³⁰⁷ and (vi) peptides and proteins.^{308,309} A noncovalent approach has also been used recently (CAT-8 **172**) to investigate the recognition of phosphorous dendrimers with aggregating peptides involved in neurodegenerative diseases.³¹⁰

2.2.2 Nitroxides with Crown-Ethers and Cryptands

The process of cation recognition by crown-ethers and analogs has been monitored by means of EPR spectroscopy, thanks to macrocycles carrying various numbers of nitroxides (Figure 31). The benzo-15-crown-5 macrocycle **178** bearing a TEMPO dimerizes in the presence of potassium affording EPR spectra in line with the 1:2 complex K^+ @ **178**.³¹¹ On the basis of a study on the changes in their EPR parameters, the dibenzo-16-crown-5 derivatives **179**, **180**, and **181** were shown to be rather poor complexing agents of cations.³¹² The di- and tetranitroxides **182**, **183**, **184**, and **187** carrying TEMPO moieties (Figure 31) have been synthesized and the binding of potassium investigated.^{313,314} The *syn*-isomer of the two stereochemically distinct chiral dinitroxides **183** and **184** showed interesting spin–spin interactions mediated by the presence or the absence of potassium, making **183** a good candidate as a cation-sensitive ionophore.

The crown-ether and cryptand nitroxides **185**, **186**, and **188** have also been prepared and did not show evidence of complex formation in the presence of alkali metal cations in methanol.³¹⁵ However, 1:1-type complexes were observed in chloroform for the cryptand-PROXYL cage **188** in the presence of $NaBH_4$. The 18-crown-6-complexed potassium salt of **189** (Figure 31) exhibited an increased solubility in ionic liquids and organic solvents of different polarity and is believed to be a useful probe to investigate these media.³¹⁶ In 1996, Turek and coworkers reported the synthesis of a di- (**190**), a tri- (**191**), and a tetra-radical (**192**), with each nitronylnitroxide moiety being

appended on a nitrogen-containing macrocycle.³¹⁷ Among them, the polyazamacrocyclic dinitroxide **190** was shown to be very sensitive to the presence of alkali metal cations in organic solvents. This phenomenon was ascribed to the ability of the complexed cation to modulate the spin–spin exchange interactions between the two neighboring radicals. A structural analog of 18-crown-6 labeled with a phenoxyl radical³¹⁸ and other crown-ethers having five to eight oxygen atoms in the ring and bearing a benzoquinone moiety³¹⁹ were prepared, which also showed molecular recognition properties toward small size alkali metal cations that were monitored by EPR. One example of a verdazyl radical appended on benzo-15-crown-5 has been reported and its dimerization in the presence of Na^+ followed by EPR.³²⁰ Finally, nitroxide-labeled crown-ethers have also been used in crystal engineering to construct molecular organic magnets³²¹ and supramolecular analogs to generate radical triplet pairs with a C_{60} appended crown-ether recognizing an ammonium bearing nitroxide.^{322,323}

2.2.3 Nitroxides with Cyclodextrins

Paton and Kaiser³²⁴ were the first to study the inclusion of a nitroxide **194** in the cavity of natural β -CD as well as the grafting of a structural analog on the macrocycle (**193**) in 1970 (Figure 32). The fact that one nitroxide grafted on a cyclodextrin (*the structures of cyclodextrins mentioned hereafter are shown in Figure 32*) has been studied at the same time as its supramolecular, noncovalent counterpart shows that these two aspects arose interest very early. However, most of the studies reported after 1970 concerned the inclusion of small spin probes almost exclusively composed of nitroxides inside the cavities of several CDs. Only 35 years later, in 2005, will the spin labeling of cyclodextrins by nitroxides be investigated again with several compounds carrying one or two nitroxides, able to self-include or not and useful to probe interactions with other entities. In these systems, the spin label is useful to monitor supramolecular interactions thanks to EPR spectroscopy.

Three years later, solid-state EPR studies on the dynamics of polycrystalline enclathrated DTBN **170** in thiourea, nitroxide **198** ($n = 5$) in β -CD,³²⁵ and 7-DSA **5** in γ -CD were reported.³²⁶ The inclusion

Figure 32 Mono- and dinitroxide spin probes used for EPR monitoring of recognition by cyclodextrins.

of TEMPONE **132** in α -CD and β -CD has also been observed quite early.³²⁷ Then, the research groups of Rassat and Janzen have extensively studied cyclodextrins by means of a large variety of spin probes. In 1975, Rassat and coworkers reported

the use of spin probes **1**, **132**, **156**, **195**, and **201–206** to study aqueous solutions of α -CD and β -CD (Figure 32).³²⁸ Chiral dinitroxide biradical **208** and **209** have then been used to study chiral recognition by β -CD.^{329,330} Inclusion complexes of

DTBN **170** in β -CD and γ -CD (solution)^{331,332} and those of TEMPO **1**, TEMPOL **156**, TEMPONE **132**, and TEMPAMINE **40** with α -CD and β -CD have been studied (solid³³³ and solution).³³⁴ β -CD has shown some protective effects regarding the kinetic of reduction of the PROXYL radical **210** by ascorbate anion in water^{335,336} as well as for DTBN and TEMPOL but not for TEMPO.³³⁷ Eastman *et al.*³³⁸ showed that nitroxides DTBN **170**, CAPRO **153**, and AMPRO **211** (Figure 32) form weak complexes with α -CD ($K_a \leq 6 \text{ M}^{-1}$) with respect to other spin probes or higher size macrocycles for which the binding constants are usually in the range 10^2 – 10^3 M^{-1} .^{339,340} In 1988, Kotake and Janzen published a series of papers describing the use of spin probes based on nitroxide **213** carrying hydrophobic *tert*-butyl and phenyl groups and functionalized analogs **214** and **215** (Figure 32). They showed that depending on the cyclodextrin added (α -CD, β -CD, and γ -CD), the nitroxides experience different environments depending on the side group included in the CD cavity (*tert*-butyl-in or phenyl-in for a bimodal-type inclusion).^{341–343} Interestingly, using the ENDOR technique, the use of prochiral spin probe **213** allowed detecting supramolecular diastereomer (two types of phenyl-in inclusion complexes) due to the inherent chiral nature of the β -CD hydrophobic cavity.³⁴⁴

Then, the same authors used α -CD, β -CD, γ -CD, and 2,6-di-*O*-methyl- β -CD (DM- β -CD) with functionalized spin probes keeping the nitroxide skeleton of **215** and replacing one phenyl group by various alkyl and cycloalkyl groups (**212**, **214**, **216** series, and **217**) to further study the bimodal-type inclusion^{345–347} and the effect of pH, pressure, and salt concentration on this phenomenon.^{348,349} The use of other probes (**212**, **219**, **220**, **221**, and **222**) even allowed identifying up to trimodal inclusion phenomena for spin probes carrying three hydrophobic, size complementary groups recognized by β -CD.³⁵⁰ An inclusion complex with an adamantanoid dinitroxide of stoichiometry 2 β -CD @ **218** has also been prepared³⁵¹ and spin–spin interactions of dinitroxide biradicals **223–225** modulated by the presence of γ -CD and various ions.³⁵² Differential pressure effects have been detected using EPR spectroscopy (β -CD spin probe **227**) with a shift of the bimodal inclusion-type complexation in favor or the *tert*-butyl group when the external pressure

increased.³⁵³ It appears that the only solvent usable for these studies is water, largely due to (i) the necessary occurrence of the hydrophobic effect and (ii) the release of “high energy” water molecules from the hydrophobic CD cavities on complexation, except in one case where ethanol was used.³⁵⁴ A good spectral resolution between the EPR signals of free and included radicals was obtained with spin probes **231–233** to investigate the cavities of α -CD, β -CD, γ -CD, DM- β -CD, and TM- β -CD, which allowed exploring the effect of several experimental parameters on the molecular recognition phenomenon.³⁵⁵ In this line, the strong sensitivity of the phosphorous splitting of hydrazyl radical **228** was exploited to study its inclusion in DM- β -CD, and a competitive method to determine the binding (association constant) of diamagnetic species based on the predetermined value of K_a of the **228** @ DM- β -CD system has been proposed.³⁵⁶ An interesting study explored the kinetics of crystal complex formation by EPR using spin probes **196**, **197**, and **200** with cyclodextrins α -CD, β -CD, and γ -CD.³⁵⁷ Lucarini *et al.* used symmetric spin probes **229** and **230** to monitor the pH-sensitive formation of the ternary complex **229** @ 2CDs and **230** @ 2CDs with β -CD, which tends to dimerize in the presence of these spin probes. The increased solubility and the protection against photodegradation of indolinone-*N*-oxyl radical **234** in the presence of RM- β -CD proved to be useful in enhancing its radical scavenging efficiency.³⁵⁸ Chiral spin probes **235–243** have also been investigated as a mean to better understand chiral recognition by inherently optically active CDs.³⁵⁹ Then, a series of papers were published about covalent nitroxide-CD architectures (i) to see whether the formation of self-included probes could be prepared and (ii) to investigate spin-labeled macrocycles to monitor the binding of other species regarding a free CD cavity. Chechik *et al.* synthesized monofunctionalized spin probes **247**, **248**, and **250** (Figure 33) based on a β -CD scaffold carrying TEMPO-type nitroxide on the narrow rim and showed that they are good candidates to monitor recognition events involving large guest molecules such as dendrimers,³⁶⁰ polymers,³⁶¹ or hydrogels.^{362,363} In 2006, a paper reported the attachment of the persistent nitroxide TIPNO on permethyl- β -cyclodextrin (TM- β -CD). The primary methoxy crown of **249** has been shown to have a pronounced effect in stabilizing the appended guest

Figure 33 Mononitroxide spin probes used for EPR monitoring of CD recognition, and covalent nitroxide appended cyclodextrins.

within the methoxy groups or perhaps hampering (steric reasons) the self-, weak inclusion of the aromatic group inside the cavity.^{364,365} The same year, Lucarini and coworkers reported the first spin-labeled dumbbell-shaped rotaxane with a bis-TEMPO stoppered axle and α -CD as the wheel component (**244**).³⁶⁶ 5-DSA **4**, 7-DSA **5**, 12-DSA **6**, 16-DSA **7**, and 5-DMS **207** were used to explore the aggregation of β -cyclodextrin in water.³⁶⁷

Bis spin-labeled cyclodextrins with TEMPO moieties attached on the primary rim, **255** and **256**, have been prepared and their host guest binding properties investigated in water by EPR, particularly the modulation of the distance between the spin centers as a consequence of guest binding inside the CD cavity.³⁶⁸ A similar approach was done using bis spin-labeled oligoethylene-glycol chains **258–261**.³⁶⁹ Lucarini and coworkers showed that it was possible to determine (i) the rate of distribution of organic substrates between cyclodextrin, micelles, and water³⁷⁰ and (ii) to explore the competitive binding of alcohols to β -CDs using **231** (Figure 32) and **253** (Figure 33).³⁷¹ A TEMPO-cyclodextrin-based rotaxane has also recently been prepared (**265**), which exhibited an improved persistency of the attached spin probe under reductive conditions.³⁷² TEMPO **1**, CAT-16 **175**, C12NO **198**, 5-DD **246**, 5-DSA **4**, and 16-DSA **7** were used to probe the cavities of α -CD, β -CD, HP- β -CD, RM- β -CD, and the water-soluble, disulfide-cross-linked, polymeric β -CD-based nanocapsules (CDS)_n.³⁷³ 5-DSA **4**, 16-DSA **7**, long alkyl chain esters derived from TEMPO **196** and **199**, and the amide analog **257** were used in a first study,³⁷⁴ and nitroxides **262** and **263** in a second,³⁷⁵ to prepare solid host guest complexes with β -CD and γ -CD and to study the temperature dependence of the guest dynamics by EPR in the solid state. Using 5-DSA **4** and the cholestane nitroxide **13**, Grammenos *et al.*³⁷⁶ investigated the action of RM- β -CD on living cells (HCT-116). EPR spectroscopy was used to explore the mobility of TEMPO **1**, 4-carboxy-TEMPO **245**, 4-amino-TEMPO **40**, and 4-hydroxy-TEMPO **156** spin probes in viscous cyclodextrin solutions.³⁷⁷ Radicals DPPH **332** (Figure 39) and CAT-16 **175** have also been used to study the interaction of human serum albumin with β -CD and sodium dodecyl sulfate.³⁷⁸

Cyclodextrins have also found an interesting application as stabilizing agents regarding nitroxide

spin adducts issued from the spin trapping of unstable free radicals by nitrones and others spin traps.^{379–382}

2.2.4 Nitroxides with Calixarenes

Calixarenes (or resorcinarenes) are phenolic (or resorcinol)-based molecules whose aromatic rings are connected by methylene bridges in a macrocyclic manner, having a relatively large variety of sizes and flexibility often distinguished by the number of repeating aromatic units inside the macrocycle.^{383–385} As for cyclodextrins, it seems that the first calixarene studies involved spin-labeled calix[4]- and calix[6]arenes **266** and **267** carrying two TEMPO-type nitroxides (Figure 34) and able to recognize alkali metal cations³⁸⁶ in a manner reminiscent of spin-labeled crown-ethers (see Section 2.2.2 above). The presence of the cation complexed by the multiple appended ethylene glycol chains modulate the distance and so the exchange interaction between the two nitroxides affording characteristic EPR patterns.

In this line, a series of nitronyl nitroxide grafted calix[4]arenes **270–273** were then developed with **272** being sensitive to Zn²⁺ complexation by two appended bipyridines,³⁸⁷ while the more spatially restricted analog **273** with two bipyridine bridging arms connecting the two calixarenes did not show cation complexation (Figure 34). Li *et al.* reported several studies of calix[4]arenes carrying one or two *tert*-butyl nitroxide moieties **274–279** in which the appended spin probes served (i) to monitor conformational exchange between the cone and the 1,2-alternate positions,³⁸⁸ (ii) to sense the presence of silver ions,³⁸⁹ and (iii) to investigate the influence of solvent, temperature, steric hindrance, and complexation of silver ions on molecular conformations of the macrocycles.³⁹⁰ Rebek and coworkers reported the use of the tetrasubstituted resorcinarene **268** with four TEMPO moieties for the recognition of small molecules and the process was followed by EPR spectroscopy.³⁹¹ The spin labeling of a calixarene analog in the 1,3-alternate conformation **280** allowed to reach new macrocyclic high-spin molecules (S = 2) with expected applications as molecular magnetic materials or magnetic chemical sensors.³⁹² As for cyclodextrins again, the noncovalent inclusion complexation

Figure 34 Covalently and noncovalently bound nitroxides for EPR monitoring of weak intra- and intermolecular interactions in calixarenes and resorcinarenes.

(exploring sizable cavities of macrocyclic cavitands) of nitroxide spin probes has been widely applied to calixarenes. In 1996, the hydrophobic cavity of **290**, a cryptophane-type facing, covalent dimer of a cyclotrimeratrylene molecule was explored by TEMPO **1**, TEMPONE **132**, TEMPAMINE **40**, and TEMPOL **156** (Figure 34).³⁹³ Later, Lucarini and coworkers used BTBN **231** to explore the cavities and binding properties of water-soluble calixarenes **281** and **282**³⁹⁴ and showed that the inclusion phenomenon of the probes produces marked differences in the EPR pattern corresponding to the included nitroxide with respect to the free radical. Solid-state supramolecular approaches featuring inclusion complexation of SG1 nitroxide **285** inside dimeric capsular hosts based on acyl-calix[4]arene **289** have also been described.³⁹⁵ Ananchenko and coworkers included TEMPO **1**, 4-methoxy-TEMPO **284**, and other 4-substituted TEMPOs in an organic zeolite host, made of crystalline **289**, and they diluted the probes with an organic counterpart fitting well the cavity of the repeating capsular assembly for expected applications as new magnetic materials, pH probes, or MRI contrast agents.^{396,397} Ramamurthy and coworkers reported nice examples of electron spin–spin superexchange³⁹⁸ and electron spin polarization transfer³⁹⁹ between included bulky

nitroxides **287** and structural analogs of **284** bearing linear alkyl chains from C2 to C10⁴⁰⁰ inside a dimerizing negatively charged capsule **291**₂ and the positively charged nitroxide CAT-1 **169** in the bulk solvent (Figure 34). A very nice and appealing self-assembling system based on resorcinarene **269**, which hexamerizes in water-saturated CH₂Cl₂ solutions, was studied by EPR using TEMPO-like spin probes **40**, **132**, **156**, **169**, and **286** to explore the inner space⁴⁰¹ and outer space⁴⁰² of the resulting giant cubic assemblies. Water-soluble calix[6]- and calix[8]arene analogs of **281** have been studied by EPR using spin probe **215** and structural analogs carrying cyclohexyl or cyclopentyl groups instead of the phenyl and for which several directional-type inclusions were identified (*tert*-butyl-in and phenyl-in and cyclohexyl-in or cyclopentyl-in inclusion complexes).^{403,404} The addition of alkali salts was observed to increase the binding of the probe toward the macrocyclic host.⁴⁰⁵ Calix[4]arene molecules carrying nitroxides are also currently being studied as new magnetic materials and contrast agents,^{406–409} but even though the radical center can be considered as a reporter of the magnetic information, it is not a spin probe in the sense developed so far in this article. There is also an example of structural analogs of **268** bearing linear alkyl chains of different length in which the four

Figure 35 CB[7] and CB[8] macrocyclic hosts which have been investigated using nitroxides in aqueous solutions.

Figure 36 X-ray view of the inclusion complex of **284** in CB[8] and supramolecular formation of the **284** @ CB[8]₃ trimer supraradical. [Reprinted with permission from Ref. 417. Copyright 2009 American Chemical Society.]

TEMPO moieties are efficient radical scavengers and the resorcinarene displays interesting antioxidant and antiradical activities.⁴¹⁰ Verdazyl radicals have also been grafted onto calixarenes with the general idea of using the verdazyl-labeled macrocycles as spin probes to monitor recognition events of the newly prepared compounds.^{411,412}

2.2.5 Nitroxides with Cucurbiturils

Cucurbit[*n*]urils (CB[*n*], *n* = 5, 6, 7, 8, and 10) are a relatively new family of synthetic macrocycles possessing a hydrophobic cavity delineated with two identical carbonyl fringed portals.^{413,414} The constricted cavity tends to accommodate a variety of guests with higher selectivity and binding constants than with the corresponding cavitands of the CD or calixarene families. Mainly due to the principle of structural complementarity, only CB[7] and CB[8] have been used until now with nitroxides and nitronyl nitroxides (Figure 35).

Lucarini and coworkers first recognized the potential of using nitroxides to investigate the interior of these fascinating macrocycles. In 2007, they published a paper in which they showed that TEMPO **1** is included easily in the cavity of CB[7] **292** ($K_a \approx 2.0 \times 10^4 \text{ M}^{-1}$).⁴¹⁵ Then in 2009, three research groups published three papers about a new supramolecular architecture based on CB[8] **293** and several nitroxides. Lucarini and coworkers focused their attention on **1**, **40**, **132**, and **168** and discovered that in the presence of CB[8], a novel spectrum was observed with seven lines of respective intensities 1:3:6:7:6:3:1 taken as indicative of a

CB[8]-mediated supramolecular interaction of three nitroxides maintained artificially, spatially close to each other.⁴¹⁶ The same year, using CB[8] and nitroxide **284**, Bardelang *et al.*⁴¹⁷ obtained crystals of a supramolecular trinitroxide whose structure was determined by X-ray diffraction and corresponds likely to that of the trimer observed by Lucarini *et al.* in solution (Figure 36). These authors also showed that small nitroxide probes can monitor the assembly of cucurbiturils in water and that CB[7] is a very good agent to protect TEMPO against bioreduction. Finally, also in 2009, the teams of Ottaviani and coworkers published a systematic investigation of a large family of TEMPO such as nitroxide (**1**, **40**, **132**, **156**, **168**, **169**, **172**, **174**, **231**, **245**, **284**, and **297–302**, Figure 35) binding to CB[8]⁴¹⁸ in which they also easily observed the formation of the paramagnetic CB[8] trimer.

In 2010, Bagryanskaya and coworkers reported the use of five-membered ring nitroxides **64**, **65**, **155**, **294**, and **295** to probe the CB[7] cavity in water.⁴¹⁹ They showed that the apparent *pK* of the investigated CB[7] mixtures with these protonable nitroxides increased with CB[7] concentration presumably as a result of the strong tendency of cucurbiturils to stabilize positively charged guests via their two carbonyl crowns. They also showed that CB[7] is a very good candidate to protect several nitroxides toward biologically relevant reductive species such as ascorbate via guest inclusion inside its cavity. Finally, Vostrikova and coworkers recently published a study on the nitronyl nitroxide **296** with CB[8].⁴²⁰ Interestingly, depending on the preparation mode of the inclusion complexes, the stoichiometry is different. In the first complex

of 1:1 CB[8]:**296** type, the macrocycle suppress the ferromagnetic interaction of the guest when considered alone. However, in the second complex of 3:2 CB[8]:**296** type, one CB[8] molecule seems to “supramolecularly clip” two guests that π - π stack inside the cavity, whereas the expelled tetramethylimidazolidinyl fragments are capped by two other neighboring CB[8] molecules. In such a structure, the ferromagnetic interaction is recovered due to the structure directing effect of CB[8], which maintain the nitroxides close enough to overlap their phenyl π -orbitals.

2.2.6 Free Radicals with Metal-Organic Polyhedra (MOP)

In 2004, Fujita and coworkers reported the use of an MOP of the octahedral cage-type **303** to include and photooxidize adamantane **308** by means of a free radical mechanism proceeding by a guest-to-host photoinduced electron transfer (Figure 37).^{421,422} Since then, his research group has published several papers about spin cages, the probing of the interior of these elegant cages by stable radicals and cage effects with respect to self-assembled free radicals and how they can mediate through space spin interactions.

For example, the nitronylnitroxide **312** was used to probe the interior of MOP **306**.⁴²³ Two molecules of nitroxide **312** are also found in the cage as a result of weak hydrophobic forces. This is interesting because there seems to be a true cage effect which “forces” the nonassociative radicals to interact through space and produce spin–spin interaction mediated by the restricted cavity of MOP **306**. Using the pH-sensitive radical **313**, they showed that the spin interaction can be controlled by pH by means of the rate of included radicals in MOP **307**.⁴²⁴ Later, they investigated the inclusion of radicals **1**, **312**, **313**, and **314** in MOPs **306** and **307** and how the cage can modulate spin interactions by means of enforced supramolecular interactions inside the restricted cavities.⁴²⁵ Thus, they showed that the doublet state of the free radicals in aqueous solutions can be switched to the triplet state in the inclusion complex and added heat as a supplementary stimulus to control guest encapsulation and release from the MOPs and so mediate intermolecular spin interactions. Finally, a new ligand based on a verdazyl radical was developed for the construction of organic spin cages (Figure 38).

A new octahedral spin cage **316** (M_6L_4 type) was prepared and new host guest spin–spin interactions were identified based on the inclusion of radicals

Figure 37 Structure of the metal–ligand cages used to encapsulate nitroxides, free radical precursors and photooxidized products. [Adapted with permission from M. Yoshizawa, S. Miyagi, M. Kawano, K. Ishiguro, M. Fujita, *J. Am. Chem. Soc.*, 2004, **126**, 9172–9173. Copyright 2004 American Chemical Society.]

Figure 38 Ligand L_1 used in the first MOP cages developed by Fujita *et al.* and a verdazyl radical-type ligand L_2 for the preparation of organic spin cages (MOP type).

312 and **315**.⁴²⁶ These new complexes are expected to find applications as new spin probe reagents and MRI contrast agents. The reaction of ligand L_2 with a palladium precursor and pyrazine afforded a novel prism-shaped organic pillared spin cage **317** for the designed inclusion of open-shell metal complexes and the finding of guest tunable spin materials.⁴²⁷

2.2.7 Self-Assembling Free Radicals

Among the free radicals that have been reported to self-assemble, there is one class of compounds responding to the presence of metal ions that can induce the self-assembly to afford molecular architectures of higher complexity. This is the case for two molecules of iminonitroxyl diradical **318** that wrap around two silver(I) ions forming a double helical structure (Figure 39).⁴²⁸ Pyrazolate nitroxides **319** and **320** form trinuclear Ni(II) meso-helicates,⁴²⁹ and a μ -NO₃[−] bridged self-assembled two-dimensional silver(I) complex of iminonitroxyl monoradical **321** has also been described.⁴³⁰ Most of the metal ion-templated assembly of nitroxides has been the object of intense studies with respect to molecular magnetism.^{431,432} A C₆₀ molecule has been labeled with a pyrrolidininoxyl-type nitroxide bearing a charged component (**322**) to enhance its tendency to self-assemble due to the amphiphilic nature of the overall structure.^{433,434}

The oligopeptide nOct-Aib-Gly-Leu-Aib-Gly-Gly-Leu-Aib-Gly-Ile-Leu-Lol has been labeled with TOAC (**27**, Figure 4) (nOct-TOAC-Gly-Leu-Aib-Gly-Gly-Leu-TOAC-Gly-Ile-Leu-Ome, nOct-TOAC-Gly-Leu-Aib-Gly-Gly-Leu-Aib-Gly-Ile-Leu-Ome, and Fmoc-Aib-Gly-Leu-TOAC-Gly-Gly-Leu-Aib-Gly-Ile-Leu-Ome) and the possibility to form supramolecular dimers and tetramers investigated (**336**, Figure 39).⁴³⁵ Supramolecular events such as the folding of bis spin-labeled porphyrin one-dimensional (1D) wires induced by the recognition of a rigid planar star-shaped aromatic compound have also been described.⁴³⁶ In this context, this may be considered as spin labeling, but in the vast majority of cases reported, the strategy relied on the grafting of open-shell molecules on compounds previously known to self-assemble in established conditions. TEMPO **1**, 4-amino-TEMPO **40**, and 4-hydroxy-TEMPO **156**

Figure 39 Self-assembling open-shell molecules.

Figure 40 Main spin traps used in EPR/ST.

Figure 41 Trapping of methyl radical with phenyl *t*-butyl nitron (PBN) and nitrosodurene (ND).

have been assembled in Laponite films exhibiting 1D antiferromagnet properties.⁴³⁷ The probes CAT-16 **175** and 5-DSA **4** have been observed to aggregate mainly due to confinement and affinity (polar) effects in the large cavities of mesoporous micelle-templated silicas.⁴³⁸ Verdazyl radicals carrying pyridine or pyrimidine groups **323**, **324**, and **325** are believed to be useful building blocks for supramolecular assemblies.⁴³⁹ Nitroxides have also been assembled via directional nitroxide–halogen

interactions in the solid state (**329**, **330**, and **331**, Figure 39).^{440,441} Nitronyl nitroxides **334** and **335** have been assembled by means of Watson–Crick base pairing using adenine and thymine bases substituted with the corresponding radicals.⁴⁴² BDPA **326**,⁴⁴³ trityl **328**,⁴⁴⁴ and DPPH **332**^{445,446} radicals have been observed to aggregate under certain conditions as for the steroid radical STNO **333**,⁴⁴⁷ which self-assembles affording fibrillar networks correlated to its organogelation abilities.

Interestingly, transduction of the chirality from the molecular to the supramolecular level is quite efficient due to the strong chiral junction zones of the gelator. PROXYL-type nitroxide **327** was shown to cocrystallize with bis-(ethylenedithio) tetrathiafulvalene affording the first purely organic

paramagnetic metal.⁴⁴⁸ The iminylnitroxide **337** has shown interesting magnetic properties in the solid state (supramolecular dimer)⁴⁴⁹ and self-organizes with nitroxide **338** using complementary multipoint hydrogen bonding.⁴⁵⁰ Nitroxide labels carrying functional groups (**156**, **159**,⁴⁵¹ **339**, **340**,

Figure 42 Main drawbacks encountered in EPR/ST experiments.

Figure 43 Half-life times of the superoxide spin adducts generated with various pyrroline-*N*-oxides.

341,^{452–454} **342**,⁴⁵⁵ and **343**)⁴⁵⁶ have been used to construct self-assembled monolayers on solid substrates^{457,458} for molecular-based spintronics devices. TEMPO **1**^{459,460} and the methyl ester of 16-DSA **7** radical⁴⁶¹ can be confined and clustered as small aggregates in the channels of the solid host compound TPP. A quite elegant approach at this interface between free radicals and supramolecular chemistry is the development of paramagnetic liquid crystals. A few approaches have been explored using nitroxides (**344** series^{462–465} and radicals **348**, **349**, and **350**)⁴⁶⁶ and trityl radical **346**.⁴⁶⁷ The nitroxide appended guanosine derivatives **345** and **347** have been observed to densely organize around potassium cations in aqueous solutions affording paramagnetic supramolecular octamers⁴⁶⁸ and hexadecamers,⁴⁶⁹ respectively. Eventually, a nitronyl nitroxide was grafted on a naphthyridine carbamate dimer (compound **351**) to target CGG/CGG triads as an addressable position in DNA duplexes.⁴⁷⁰ Nitroxides **352** and **353** have shown interesting magnetic properties in the liquid⁴⁷¹ and organized solid⁴⁷² phases, respectively.

Some ribonucleosides have been labeled by nitroxide spin labels with addition of a—N(O[•])—*t*Bu group on the base part of the structure but the recognition properties were not investigated.^{473,474} The spin-labeled nucleoside **354** has been synthesized and included in the sequence of oligodeoxynucleotides.⁴⁷⁵ The corresponding EPR spectra were sensitive to the degree of hybridization of the complementary strand and spin–spin interactions modulated by the distance between the spin centers. Molecule **355** with π -conjugated nitroxide spin label forms 1D ferromagnetic chains in the solid state.⁴⁷⁶ Finally, the water-soluble trityl radical Ox063 **3** has been reported to trigger the formation of polyelectrolyte networks in a structural manner reminiscent of a zip-like cooperative binding effect.⁴⁷⁷

In conclusion, after the first advances in the use of spin probes/EPR to investigate the hollows of a variety of structures and materials, the rules of supramolecular chemistry started to add a predictive component in order to obtain structures of higher complexity and seek for advanced material applications. In this line, one growing fascinating field is that of paramagnetic, crystalline host compounds in which the building block of the supramolecular solid framework is carrying a free radical. Some crystals

have already appeared which hold great promises for the development of supramolecular solid-state recognition with paramagnetic compounds. Some emerging properties as, for example, modulation of the magnetic properties by the careful and subtle use of the (also emerging) rules of crystal engineering are likely to open new fields of development in the coming years.^{478–480} Paramagnetic open frameworks provide the opportunity to entrap functional guests to control bulk solid magnetic properties at will.

3 SPIN TRAPPING

3.1 Principle of Spin Trapping

The trapping of a transient free radical Y[•] with a diamagnetic spin trap T to generate a persistent spin adduct (TY)[•] which, under the actual reaction conditions, could be characterized by its EPR spectrum, constitutes the well-known spin trapping technique, hereafter abbreviated EPR/ST. The spin adduct radical (TY)[•] can be considered as reporting

on the radical chemistry occurring in the system under investigation.

EPR/ST was introduced in the late 1960s^{481–485} and since then it is commonly employed in various domains: organic chemistry, environmental chemistry, toxicology, biology, materials, food chemistry, and so on, and its advantages and drawbacks are largely debated.^{379,486–494} In spite of the enormous progress made in five decades, EPR/ST is still faced with limitations particularly for the investigation of *in vivo* free radical processes. The important literature on EPR/ST illustrates the wide scope of its applications and the continuing efforts to improve its efficiency and reliability.

3.2 Main Spin Traps

A large variety of trapping agents has been developed since the introduction of the spin trapping technique, some are depicted in Figure 40.

The most commonly used spin traps are open-chain (**356** and **357**) or five-membered ring

cyclic nitrones (358–360) and aliphatic or aromatic nitroso compounds (361–363). In both cases, the resulting spin adducts are nitroxides (Figure 41) whose half-life times depend strongly on the type of the trapped radical, the choice of the spin trap, and the experimental conditions. In spin adducts derived from nitroso derivatives (ND-CH₃, Figure 41), the trapped radical is directly bound to the nitrogen of the aminoxyl function, whereas in those from nitrones, it is bound to the carbon atom adjacent to it (PBN-CH₃, Figure 41). The EPR spectrum of ND-CH₃ is a triplet of quartet ($A_N = 1.370$ mT, $A_H(3\text{ H}) = 1.217$ mT, in benzene)⁴⁹⁵ and its formation in a chemical process investigated with EPR/ST can be considered as an evidence of the formation of methyl radicals. The spectrum of PBN-CH₃ is a triplet of doublet ($A_N = 1.496$ mT, $A_H(H_\beta) = 0.375$ mT, in benzene) that contains no direct information on the trapped methyl radical. However, for a PBN spin adduct, the magnitude of the β -hydrogen hyperfine coupling depends on the type of the trapped radical (PBN-OCH₂CH₃: $A_N = 1.415$ mT, $A_H(H_\beta) = 0.250$ mT, in ethanol; PBN-OSiPh₃: $A_N = 1.450$ mT, $A_H(H_\beta) = 0.560$ mT, in toluene), and it can be cautiously used for its identification.

Apart from nitrones and nitroso compounds, many other molecules undergo radical addition leading to more or less persistent adducts. These unconventional spin traps, such as 364, 365, and 366,⁴⁹⁶ can be specific for a particular family of radicals and should not be disregarded when designing an EPR/ST experiment.

It is worth mentioning that the results of an EPR/ST experiment must be interpreted with caution, since the EPR observation of a spin adduct does not necessarily imply the occurrence of a direct free radical trapping process (Figure 42).^{497–502} For example, the formation of the ND-Me spin adduct, observed when MeI is reacted with *n*BuS[−]Na⁺ in benzene in the presence of ND, does not result from the direct trapping of methyl radicals (Figure 42).⁵⁰¹ The chemical process corresponding to (2) (Figure 42) is called *inverted spin trapping*.⁴⁹⁹

Moreover, the failure to detect a spin adduct does not necessarily mean that radical species were not present in the investigated system. For example, nitroxide spin adducts can be rapidly reduced to EPR-silent hydroxylamines and that constitutes a main limitation of *in vivo* EPR/ST experiments.²³⁵

During the past three decades, EPR/ST has been extensively used to investigate the contribution of free radicals to various biological processes, and problems connected to oxidative stress have received a special attention.^{382, 487–493} The superoxide radical anion (O₂^{•−}) and the hydroxyl radical (HO[•]) play a major role in oxidative stress, and important efforts have been devoted to the search of spin traps especially suited to characterize these species (see **Oxidative Damage to Proteins**). Nitroso compounds are poorly water soluble and they yield short-lived spin adducts with oxygen-centered radicals, then, their use in biological EPR/ST is rare. Nitrones are reasonably water soluble, poorly toxic, and they usually generate more or less persistent spin adducts with oxygen-centered radicals. Although the half-life time of the spin adduct of superoxide with DMPO (DMPO-OOH, Figure 43) is only 1 minute in phosphate buffer at pH 7.2, this popular spin trap has been widely used in biological EPR/ST. In 1995, Tordo and coworkers⁵⁰³ showed that replacing one methyl group of DMPO with a diethoxyphosphoryl group (DEPMPO, Figure 40) leads to a significant increase (about 15 times) of the half-life time of the corresponding superoxide spin adduct (DEPMPO-OOH, Figures 43 and 44). Since then, a large number of pyrroline-*N*-oxides (360, Figure 40) bearing an electron-withdrawing group on C5 and various substituents on C3 and (or) C4 have been prepared,^{379, 493, 503–506} and for some of them, the half-life time ($\tau_{1/2}$) of the corresponding superoxide spin adduct is larger than 30 minutes.

The values of $\tau_{1/2}$, in phosphate buffer at physiological pH, for the superoxide spin adducts of DMPO, DEPMPO,⁵⁰³ Mito-DEPMPO,⁵⁰⁴ EMPO,⁵⁰⁵ AMPO,⁵⁰⁶ and *trans*-3,5-EDPO⁵⁰⁷ are shown in Figure 43, and the EPR spectrum of Mito-DEPMPO-OOH is shown in Figure 44.

4 CONCLUSION

The microenvironment and the motional dynamics of a free radical influence strongly the shape of its EPR signal; thus, nitroxides and to a lesser extent trityl radicals are routinely used for EPR probing of various chemical and biological systems. In this article, we have illustrated the strong potential of this approach in different domains: determination of the structure of biological membranes, proteins,

Figure 44 Experimental (a) and calculated (b) EPR spectra of Mito-DEPMPO-OOH spin adduct at rt in phosphate buffer, pH 7.3.⁵⁰⁴

DNA, RNA, and supramolecular assemblies and pH measurements, oxymetry, detection of transient radicals, and so on. In the next few years, we can expect that the design of new spin labels, spin probes, and spin traps and developing the use of pulsed and high-frequency EPR techniques will expand the frontiers of this research area.

Radical Thiol–X Click Chemistry

Niels ten Brummelhuis and Helmut Schlaad

Max Planck Institute of Colloids and Interfaces, Department of Colloid Chemistry, Potsdam, Germany

1 INTRODUCTION

The free-radical addition of thiols or mercaptans to unsaturated compounds (Scheme 1), which has been known for more than 100 years,¹ has become a well-established and versatile tool in organic synthesis² as well as in macromolecular and surface chemistry.^{3–9} Major reasons for the popularity and success of the hydrothiolation reaction are the ease and convenience of handling, its robustness, and its wide applicability. Owing to the often high reactivity and low selectivity of radical species, addition reactions may be accompanied by side reactions such as, for instance, radical–radical coupling, chain transfer, and polymerization as well as by *cis/trans* isomerization of olefins. For properly chosen reaction conditions, however, the radical additions of thiols to carbon–carbon double bonds (thiol–ene) and triple bonds (thiol–yne) can proceed smoothly in the absence of side reactions and even have “click” characteristics.^{10–15} The concept of “click” chemistry, as was introduced by Sharpless *et al.* 10 years ago,¹⁶ demands that a reaction be modular and wide in scope, gives quantitative yields, generates (if any) inoffensive by-products which can be removed by nonchromatographic methods, and is stereospecific (but not necessarily enantioselective). Practically, the process should be simple to perform and be accomplished with readily available reagents either in bulk or in environmentally benign solvents, and the products should be easily isolated. A click reaction ought to

be fast and be selective for a single product, and hence exhibit orthogonal reactivity. Polymer click chemistry further demands that reactants should be used in stoichiometric amounts, especially when it concerns polymer–polymer coupling, and that the products can be purified on a large scale.¹⁷

Most of these criteria can be readily fulfilled by radical thiol addition reactions, though quantitative yields can sometimes be achieved only when the thiol is used in (large) excess. Apart from radical reactions, thiols can react in a number of nucleophilic addition and substitution reactions. Nucleophilic thiol–X reactions, likewise classified as click reactions, include the base-catalyzed Michael-type thiol–ene addition to activated double bonds bearing electron-withdrawing groups,¹⁸ thiol–isocyanate addition,¹⁹ thiol–oxirane addition,²⁰ and thiol–halogen substitutions^{21,22} (Scheme 1). The chemical structures of reactants and reaction conditions are therefore crucial parameters deciding the orthogonality and click characteristics of a thiol–X reaction. For other reactions of the click family, such as the 1,3-dipolar Huisgen azide–alkyne cycloaddition which is regarded as the gold standard of click chemistry,¹⁶ orthogonality may not be an issue but the required usage of explosive compounds (azide) and potentially toxic transition-metal (copper) catalysts can be.

In the first part of this article, the mechanism of radical addition of thiols to carbon–carbon multiple bonds is briefly discussed. Description of the mechanism may not be all comprehensive but

Scheme 1 Radical and nucleophilic thiol-X click reactions.

restricted to what is relevant for click chemistry. The following parts are devoted to the application of radical thiol-X chemistry in synthetic organic, macromolecular, and colloid/surface chemistry. Published work until December 2010 has been considered for this review.

2 MECHANISM OF RADICAL THIOL-X ADDITION

Radical thiol-X chemistry is the radical addition of thiols to unsaturated carbon-carbon bonds, either to alkenes or alkynes, proceeding via a chain process involving initiation, propagation and chain transfer, and termination steps.^{2-4,12,23} Mechanisms and possible side reactions of radical thiol-ene and thiol-yne addition reactions will be described first, followed by a discussion of different types of initiation systems that may influence the efficiency of the process.^{4,24}

The addition of a thiol to a carbon-carbon double bond is a three-step process (Scheme 2): generation of the thiyl radical, reversible addition of the thiyl radical to the double bond, preferentially in anti-Markownikoff orientation, and chain transfer of hydrogen to the intermediate carbon radical species. For radical thiol-ene chemistry, this hydrogen is ideally provided by another thiol group, thereby creating another thiyl radical. However, chain transfer may also occur via solvent molecules, especially halocarbons and aromatic hydrocarbons. The propagation/chain transfer cycle can turn several hundreds to thousands times before termination occurs by radical-radical recombination. Generally, the second step of chain transfer is the rate-limiting step. Therefore, the structure of the thiol (and solvent) strongly influences the kinetics of the reaction. For instance, aromatic thiols are far more efficient chain transfer agents than aliphatic thiols because of the possible stabilization of the radical species by resonance. Also, the thiyl radical addition to carbon-carbon double bonds is reversible, and the intermediate

Scheme 2 General mechanism of radical thiol–ene addition.¹³

carbon radical may eliminate a thiyl radical with the formation of an alkene under cis/trans isomerization.²⁵ Stereochemistry can be maintained when the intermediate radical cannot disturb this stereochemistry as, for instance, for unsaturated rings, for which the product (mixture) can be determined by the relative rates of proton transfer to the carbon radical.

The rate of addition to alkenes is strongly dependent on the substituents. For aliphatic molecules, the addition rate decreases in the series from strained cycles (e.g., norbornene), to terminal alkenes, to cis double bonds, to trans double bonds.²⁶ If other neighboring groups are present, in vinylic as in an allylic position, the prediction of the reactivity becomes more complicated and in some cases also mixtures of products are obtained. The presence of halogens, heteroatoms, or groups containing heteroatoms results in the formation of products with the sulfide group on the vicinal position. Thioethers or halogens in allylic position can lead to a β -elimination upon thiyl radical addition to the double bond, yielding a new radical (either another thiyl or a halogen radical) and a new double bond (allyl sulfide). The radical addition to conjugated π systems affords a delocalization of the radical, so that chain transfer of a proton can occur on multiple positions, thereby yielding a mixture of products. When strained cycles, for example, cyclopropanes or oxiranes, are present as substituents, the carbon

radical formed after addition can also delocalize by a ring-opening mechanism, resulting in the formation of mixtures of isomeric structures after proton transfer.²

The mechanism of thiyl radical addition to carbon–carbon triple bonds (Scheme 3) is similar to the aforementioned chain process.²³ Addition of a thiyl radical to the alkyne moiety proceeds with anti-Markovnikoff orientation, again producing the more stable carbon radical. Proton transfer yields a vinyl thioether (sulfide) as intermediate product. Generally, the cis product of the first addition is found in higher abundance, which may be attributed to a preferential hydrogen transfer to the cis radical or the conformation of the intermediate radical. The intermediate alkene can participate in a thiol–ene addition, which usually yields the vicinal product (the geminal product is formed only when the neighboring group is aromatic; dithioacetals are formed in the course of nucleophilic thiol–yne additions).

The intermediate vinyl thioether is supposed to have a considerably higher reactivity toward thiyl radical addition than the alkyne.² This may hold true for thiol–yne photopolymerizations, for which the second addition was found to be about 3 times faster than the first,²³ but seemingly not for the thiyl radical addition to cyclooctyne²⁷ or alkynyl amino acids.²⁸ In contrast, the nucleophile-catalyzed

Scheme 3 General mechanism of radical thiol-yne addition.²³

addition of thiol to a vinyl thioether is about 1000 times slower than that to the triple bond.²⁹

The aforementioned mechanism of radical thiol additions indicates the possible occurrence of a number of side reactions. Radical thiol-X additions do not generally proceed as click reactions except for a limited number of cases (without severely losing the characteristics of being modular and wide in scope). Regarding the nature of the unsaturated group, terminal alkenes or alkynes and cyclic structures such as norbornene are preferred. In case of electron-deficient alkenes, for example, (meth)acrylates, special care should be taken to avoid (homo)polymerization of the alkene moieties. Furthermore, the presence of other species that can participate in radical reactions should be avoided, for instance, hydroquinones, anilines, or sulfoxides. On the other hand, thiol-ene single additions (but not polymerizations) can be performed in the presence of air or oxygen without severely affecting the kinetics but introducing an additional hydrogenperoxide moiety.⁴ It should also be considered that bases (amines) can deprotonate thiols ($pK_a \sim 10$) and inhibit the radical addition reaction.

Radicals can be generated in a variety of ways, the most straightforward ones involving the use of thermal or photochemical initiators (see **Overview of Radical Initiation**). Radical initiators can

be divided into two different classes, namely, initiators undergoing cleavage (type I) and initiators abstracting hydrogen (type II).²⁴ Examples of type I initiators include azo compounds (e.g., azobisisobutyronitrile (AIBN)) and peroxides (e.g., benzoyl peroxide (BPO)) and also photoinitiators (e.g., (2,4,6-trimethylbenzoyl)diphenylphosphine oxide (TMDPO) and 2,2-dimethoxy-2-phenyl acetophenone (DMPA)). These compounds undergo cleavage upon heating or irradiation with UV light with the formation of two radical species. Either one or both radicals can add to the unsaturated carbon-carbon bond directly or abstract hydrogen from a thiol to initiate the addition reaction. Type II photoinitiators, for instance benzophenone, react in their triplet excited state with a hydrogen donor, that is, thiol, to generate the thiyl radical and initiate the addition reaction.²⁴

Thiyl radicals can also be directly generated by either applying high temperature (typically far over 100 °C) or irradiation with UV light (typically using UV lamps with $\lambda_{\max}$ at 254 or 365 nm) or sunlight⁴ or exposure to a ⁶⁰Co radioactive source.² The direct generation of thiyl radicals is preferred for thiol-X click chemistry, as the formation of undesired by-products from chemical initiator fragments is avoided.

3 APPLICATIONS OF RADICAL THIOL-X CLICK CHEMISTRY

Radical thiol additions to unsaturated carbon–carbon bonds may have the characteristics of click reactions as discussed earlier. However, the intermediate radical species tend to undergo side reactions, thus reducing the yields as well as the functionality and purity of the crude products. Crucial parameters for obtaining click characteristics are not only the chemical structures of the reactants (e.g., substitution of the carbon–carbon multiple bond and reactivity of the thiol) but also the nature of the radical source and of the solvent. The relative amounts of the reactants should be chosen such that a quick addition and also hydrogen transfer are always assured. The thiol should therefore always be used in excess. For heterophase reactions, for example, inside micelles or on surfaces, the local concentration and accessibility of unsaturated groups need to be considered.

The following sections of this article discuss applications of radical thiol–X (X = ene and yne) click chemistry for the synthesis of functional materials. These sections comprise organic chemistry (synthesis of organic molecules, peptides, and dendrimers), macromolecular chemistry (synthesis and modifications of polymers and biomacromolecules, hyperbranched polymers, and polymer networks), and colloids and interfaces (modifications and functionalizations of organic and inorganic surfaces).

3.1 Organic Chemistry

Though radical thiol–X click chemistry has mostly been applied in macromolecular chemistry, the chemistry has been used earlier in the synthesis of especially bioorganic molecules. However, even when the conversion of reactants is quantitative, the products are often subjected to elaborate purification, for instance (flash) column chromatography. Such reactions, very strictly speaking, cannot be considered as click reactions. However, this does not mean that these reactions are less useful or not efficient. Especially, short reaction times and tolerance toward most functional groups make this synthetic pathway very attractive for the production of a palette of different compounds, including functional vegetable oils, saccharides, peptides, and dendrimers.

Scheme 4 Photoinduced thiol–ene click coupling for the synthesis of thiodisaccharides. [Redrawn from Ref. 34. © American Chemical Society, 2009.]

3.1.1 Functional Vegetable Oils

Radical thiol–ene chemistry was used for the functionalization of unsaturated vegetable oils from renewable resources to make them more stable toward oxidation and better suitable for different applications such as lubrication or synthesis of polyesters.^{30,31} For the photoadditions of butanethiol to canola or corn oils (initiated by UV light, $\lambda < 325$ nm, $[\text{SH}]_0/[\text{C}=\text{C}]_0 = 6$), the conversion of the cis double bonds was $\sim 90\%$ or higher after 8 hours. However, the crude products consisted of mixtures of components, and the highest isolated yield of the purified product was about 61%.³⁰ Thiol additions to methyl-10-undecenoate and derivatives from castor oil, on the other hand, showed all the features of a click reaction (Figure 1).³¹ These examples highlight the importance of the degree of substitution at the double bond for click addition of thiols.

3.1.2 Saccharides and Glycoclusters

Thiol–ene chemistry is a well-established tool in carbohydrate synthesis. Lindhorst *et al.* applied the thermal addition of 2-mercaptoethanol to 3,6-diallyl-protected sugars (initiator: AIBN) as an intermediate step in the synthesis of glyco-dendrons.³² By irradiation of a methanolic suspension of perallylated D-glucose and cysteamine hydrochloride with UV 254-nm light, the pentavalent carbohydrate structure was produced in virtually quantitative yield. Likewise, Klaffke *et al.* applied the same procedure for the synthesis of a series of amine-functional mono- to trisaccharides in 70–80% yield.³³

Dondoni *et al.* described the photoinduced click coupling (irradiation at 365 nm in the

presence of DMPA as sensitizer) of anomeric sugar thiols with sugar alkenes.³⁴ The 1,6-linked *S*-disaccharides were obtained in good to excellent yields ($>75\%$) and high diastereoselectivities (up to 99%) (Scheme 4).

The same group also described the modification of calix[4]arenes with thiosugars to yield glycoclusters.³⁵ The reactions were performed in dichloromethane solution in air with irradiation at 365 nm in the presence of DMPA. The positions (above and/or below the rim of the macrocycle) and nature of the unsaturated groups (double or triple carbon–carbon bond) could be changed, thereby obtaining a number of different molecules with a predefined number of sugar moieties (Scheme 5a). Furthermore, by orthogonal combination of the Huisgen azide–alkyne cycloaddition and radical thiol–ene addition, different types of sugar moieties could be incorporated regioselectively to yield Janus-type glycoclusters (Scheme 5b).

Likewise, glycoclusters based on polyhedral oligosilsesquioxanes (POSS) were prepared (Scheme 6).³⁶ Octavinyl POSS, which is a commercially available compound, was reacted with sugar thiols ($[\text{SH}]_0/[\text{C}=\text{C}]_0 \sim 4$) in a 1:1 mixture of water/tetrahydrofuran through irradiation with UV light (254 nm) in the presence of catalytic amounts of AIBN. Purification of the crude products by gel filtration afforded the pure glycoclusters in $\sim 70\%$ yield; unreacted sugar could be recovered in pure form.

3.1.3 Functional Amino Acids and Peptides

The modification of cysteine units is commonly done via nucleophilic Michael addition to maleimides or (meth)acrylates,⁷ but recently also different thermal and photochemical

Scheme 5 (a) Photoinduced multiple thiol-ene click coupling for the synthesis of calix[4]arene-based *S*-glycoclusters. (b) Orthogonal glycosylation of calix[4]arene applying sequential Huisgen azide-alkyne cycloaddition (first step) and radical thiol-ene addition (second step). routes of radical thiol–ene additions have been described.

Differently protected and unprotected cysteines were treated with 1-alkenes in the presence of AIBN as radical source at 90 °C in organic solvents.³⁷ Importantly, the S-alkylated cysteines

could be obtained in high yields and without racemization.

Short peptides (4–16 amino acids) with an alternating sequence of L-leucine and L-allylglycine were reacted with hydrophilic thiols, namely, cysteamine hydrochloride, thioglycolic acid, and

2,3,4,6-tetra-*O*-acetyl- β -D-glucopyranose.³⁸ The radical additions were initiated by AIBN at 70 °C and run in either dimethylformamide (DMF) or toluene solution depending on the solubility of the thiol. For all cases, the conversions of allyl groups were quantitative within 20 hours. The shorter peptides, but not the 16-mer one, could be isolated in good to excellent yields.

Dondoni and Massi *et al.* used the hydrothiolation reaction for the coupling of allyl *C*-glycosides with cysteine and glutathione.³⁹ Best yields, that is 90% or higher, were achieved when reactions were performed in 0.5 M DMF solution with irradiation at 365 nm and DMPA as sensitizer; the thiol was used in threefold excess with respect to double bonds. This procedure was also successfully applied for the photoinduced glycosylation of a synthetic nonapeptide carrying a single cysteine unit and of native globular bovine serum albumin (BSA) (Scheme 7), as confirmed by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry. Reactions were conducted in dimethylsulfoxide (DMSO), though sulfoxides can act as a radical scavenger and thiol oxidation agent,⁴⁰ and phosphate buffer under argon atmosphere.

The photochemical coupling of protected cysteine derivatives to 1-alkenes was studied by Kunz *et al.* as model reactions for the conjugation of amino acids and peptides to make BSA-glycopeptide vaccines.⁴¹ Reactions were performed either with irradiation at 254 nm or thermal initiation with radical starter in aqueous or alcoholic solutions; the yields of purified compounds were between 31% and 88%. The coupling of thiol-terminated glycopeptide antigen to allylether-modified BSA, as exemplarily shown in Scheme 8, was performed with UV 254-nm irradiation in aqueous phosphate buffer solution under argon. The antigen-BSA conjugate contained on average eight glycopeptides per molecules BSA, as indicated by MALDI-TOF mass spectrometry, corresponding to a degree of functionalization of 32%. This procedure cannot, contrary to the previous example described by Dondoni and Massi, be considered as a click reaction even though a larger number of glycopeptide chains could be attached to BSA.

Recently, Dondoni *et al.* also reported the nucleophilic functionalization of cysteine derivatives with propargyl bromide and subsequent thiol-yne addition of sugar thiols, that are thioglucose,

galactose, and lactose, and thiol-functionalized biotin (Scheme 9).²⁸ The photoinduced double addition of thiosugar to alkynyl amino acids and peptides was found to proceed, under the experimental conditions noted in Scheme 9a, smoothly in quantitative yield (>95%). Making use of the fact that the radical addition to the internal vinyl thioether was slow as compared to the terminal alkyne, it was also possible to perform a one-pot sequential addition of two thiol radicals generated by different thiols, that is, sugar thiol and biotin thiol (Scheme 9b). However, the mixed addition product could only be isolated in a low yield of 34%.

Similarly, Anseth *et al.* studied oligopeptides containing 1–3 lysine units and coupled 4-pentynoic acid to the ϵ -amino groups to introduce alkyne groups in the side chains.⁴² Thiol-yne photochemistry was then applied to achieve clustered peptides in purified yields of 77–87%.

The photochemical click functionalization of propargyl esters with various thiols, including a derivative of proline (captopril), has also been described.⁴³

3.1.4 Cyclic Oligopeptides and Macrocycles

Anseth *et al.* applied the radical thiol-ene coupling for the synthesis of cyclic peptides.⁴⁴ A peptide sequence bearing an alkene group, either allyl or norbornene, in the first amino acid and a protected thiol residue in the last (cysteine) was prepared using solid-phase synthesis. While still attached to the resin, the cysteine was deprotected and the sample was irradiated with UV light (365 nm) in the presence of DMPA. The radical thiol-ene reaction between the two reactive groups in the peptide sequence led to a cyclization of the peptide as shown in Scheme 10a. Building on this work, the same group used sequential thiol-ene and thiol-yne photochemical reactions for the synthesis of cyclic multivalent peptides.⁴² The aforementioned cyclic peptide was extended by two glycines and a cysteine (isolated yield: 15%). This cyclic peptide was then attached to linear oligopeptides bearing up to three side-chain triple bonds via thiol-yne addition (Scheme 10b). The cyclic dimer and tetramer were isolated in 48% and 11% yield, respectively, but the cyclic hexamer could not be

observed. The decreasing yields of clusters with increasing number of cycles were attributed to steric hindrance.

Li *et al.* were able to prepare macrocycles and rotaxanes via disulfide coupling and thiol–yne photochemistry (Scheme 11).⁴⁵ A bis(triethylene glycol)-naphthalene was thiolated by esterification with thioglycolic acid and then assembled into a cycle with secondary dibenzylammonium ions at high concentration. The cycle was closed by addition of prop-2-ynyl benzoate under irradiation at 365 nm in the presence of DMPA. The desired macrocycle was obtained in 80% yield. The use of a dumbbell-shaped dibenzylammonium salt template resulted in the formation of a rotaxane.

3.1.5 Dendrimers

Dendrimers are repeatedly branched, monodisperse molecules having rather spherical shape (see the structure in Scheme 12) and are classified by generations G1, G2, G3, ..., referring to the number of repeated branching cycles during the synthesis. Dendrimers are synthesized by either convergent or divergent processes. Thiol–X chemistry has exclusively been applied in divergent reaction processes: that is, starting from a multifunctional core, which is then extended to the outward using AB₂ monomers. Importantly, in order to obtain the desired perfect dendrimer structure, which is usually confirmed by nuclear magnetic resonance (NMR) spectroscopy and MALDI-TOF mass spectrometry,

Scheme 10 (a) On-resin cyclization of oligopeptides⁴⁴ and (b) synthesis of clustered peptides⁴² using thiol–ene/thiol–yne photochemistry. [Redrawn from Refs 42 and 44. © Royal Society of Chemistry, 2010.]

Scheme 11 Synthesis of sulfuric macrocycle by thiol-yne photochemistry. [Redrawn from Ref. 45. © American Chemical Society, 2010.]

every reaction step must click and come to full completion.⁹

Hawker *et al.* applied nucleophilic epoxy-amine and radical thiol-ene additions for the synthesis of dendrimers.⁴⁷ The core molecule 1,4-bis(aminomethyl)benzene was first reacted with allyl glycidyl ether (AB₂ monomer), and subsequently the allyl groups were modified with 2-mercaptoethylamine hydrochloride. The final G3 dendrimer could be further functionalized with monomethyl(triethylene glycol)mercaptane.

The synthesis of a G4 dendrimer starting from 2,4,6-triallyloxy-1,3,5-triazine as tris-alkene core has also been described.⁴⁸ The AB₂ monomer 1-thioglycerol was added to the core by irradiation at 365 nm in the presence of trace amounts of DMPA. The reaction was performed in air and came to completion within 30 min when at least 1.5 equiv of AB₂ monomer were used. The OH functionalities were subsequently converted into ene functionalities by esterification with 4-pentenoic anhydride to yield [G1]-ene₆. Repetition of this procedure afforded the fourth-generation dendrimer [G4]-ene₄₈. Dendrimers were purified by simple precipitation into diethyl ether and recovered in 90+ % yield. Additionally, the double bonds on the surface of the dendrimers could be click-modified with functional thiols.

The combination of thiol-ene chemistry and esterification reactions was further applied for the generation of a dendritic library from different

core molecules and AB₂ and CD₂ monomers (Scheme 12a).⁴⁶ For instance, a fifth-generation dendrimer [G5]-OH₉₆ could be obtained starting from a triallyl isocyanurate core (Scheme 12b). Importantly, these coupling chemistries eliminate the traditional need for protection/deprotection steps and afford dendrimers in high yield and purity.

Stenzel *et al.* applied a thiol-yne and esterification process to obtain the third-generation dendrimer having as much as 192 hydroxy groups, [G3]-OH₁₉₂.⁴⁹ The core molecule employed was a trifunctional alkyne and the AB₂ monomer was 1-thioglycerol; esterification was achieved with acetylene anhydride. Dendrimers were obtained in high purity, though yields were not given. Furthermore, [G1]-yne₁₂ was successfully reacted with thioglycolic acid to give a carboxylated [G1]-COOH₂₄.

Multifunctional branched structures and dendrimers based on organosilanes were synthesized by Rissing and Son (Scheme 13).^{50–52} Tetravinylsilane was functionalized with 3-mercaptopropyl-trimethoxysilane (MPTMS) by thiol-ene photoaddition with irradiation at $\lambda_{\text{max}} = 365$ nm (broadband emission of a sunlight bulb) in the absence of a photoinitiator. The methoxy groups were exchanged for vinyl groups in a Grignard reaction using vinyl magnesium bromide. Repetition of the procedure gave the G3 dendrimer in quantitative yield. The synthesis of the higher generation dendrimers required the use

Scheme 12 (a) Core molecules and monomers employed for the synthesis of dendritic libraries. (b) Synthesis of fifth-generation dendrimer using thiol-ene/esterification chemistries. [Reproduced from Ref. 46. © American Chemical Society, 2010.]

Scheme 13 Synthesis of carbosilane-thioether dendrimers by thiol-ene and Grignard reactions (Vi = vinyl). [Reproduced from Ref. 52. © American Chemical Society, 2009.]

of a photoinitiator in the thiol–ene reaction step. The production of a G6 dendrimer failed, likely because of the extremely high concentration of vinyl groups.

Radical thiol–ene photochemistry has also been applied in combination with the Huisgen azide–alkyne click reaction by Hawker *et al.* (Scheme 14).⁵³ The highly orthogonal and time-efficient protocol of radical thiol–ene chemistry and copper-catalyzed azide–alkyne cycloaddition allowed the synthesis of a G6 dendrimer within a single day. The core containing three alkene groups was functionalized with a thiol containing two azide groups, which were in turn functionalized in an azide–alkyne cycloaddition, and so on. The reaction cycles proceeded smoothly to the generation four dendrimers. Some dendrimer–dendrimer cross-coupling through radical recombination occurred in the fifth-generation growth step.

3.2 Macromolecular Chemistry

Especially in macromolecular chemistry, the radical thiol–ene reaction has found widespread acceptance and application. Early examples of thiol–ene reactions, such as for instance the step-growth polymerization and the modification of diene rubbers, may not be classified as true click reactions, as discussed below; nevertheless, the chemistry was very convenient and often highly effective.

3.2.1 Functional Polymers

Even though this chemistry was known since the beginning of the last century,¹ there were just a few reports published until 2003 (most of them dated 1990 or later) dealing with the use of radical thiol additions for the modification of diene rubbers, polybutadienes (Boutevin *et al.* and others),^{54–66} and polysiloxanes (Boileau *et al.*)^{67,68} and for polymer end functionalization (Kataoka *et al.*).⁶⁹ Since 2004, the radical thiol–(1,2-)polybutadiene modification has been explored extensively for the generation of functional homopolymers and block copolymers, including polyelectrolytes and biohybrid polymers (Schlaad *et al.*^{70–77} and others^{78–81}) and for the thiolation of polyurethanes.⁸² The reaction was

demonstrated to be modular and wide in scope, but is plagued by some side reactions, especially intramolecular cyclization on the polymer backbone through addition of the intermediate carbon radical to a neighboring double bond (Scheme 15).^{71,76,78,80} Degrees of functionalization of up to 80% at full conversion of double bonds could be achieved. Nevertheless, thiol–polybutadiene addition does not qualify as a polymer click reaction. Thiol–ene photoaddition to polyisoprenes was found to occur preferentially on the 1,2-units but not on 1,4- and 3,4-units, thus in a non-click fashion.⁸³

From the insight and experience gained from these examples, radical thiol–ene chemistry was developed in a way that it proceeds as a click reaction.

Main-/Side-Chain Functional Polymers

Schlaad *et al.* were the first to use the term “thio-click” for a radical thiol–ene reaction system, namely for the photochemical thiolation of poly[2-(3-butenyl)-2-oxazoline] homopolymers and copolymers with a series of different thiols (Scheme 16).⁸⁴ The increased distance between intermediate radical and neighboring double bond, as compared to 1,2-polybutadiene, disfavors any intramolecular cyclization reaction, thus promoting a side-reaction-free thiol click addition. In order to minimize radiation damage to the polymer and to keep radical concentration low (to avoid radical–radical coupling), thiyl radicals were generated directly by irradiation with UVA light ($\lambda > 300$ nm) in the absence of a photoinitiator.

Since then, several other groups (Hawker *et al.* and others) have shown that the same click character can be obtained for other types of ene polymers (Figure 2) and thiols.^{85–89} Thiol–ene “clickable” copolymers include poly[(4-(3-butenyloxymethyl)-styrene)-*co*-styrene] and poly[(3-butenyl methacrylate)-*co*-(methyl methacrylate)],⁸⁵ which were synthesized by controlled radical polymerization techniques (RAFT (Reversible Addition Fragmentation chain Transfer) and ATRP (Atom Transfer Radical Polymerization), respectively), poly(ethylene oxide)-*block*-poly[(6-allyl- ϵ -caprolactone)-*co*-(ϵ -caprolactone)],⁸⁵ poly(ethylene oxide)-*block*-poly(DL-allylglycine),⁸⁶ poly(allyl glycidyl ether)-*block*-poly(ethylene oxide)-*block*-poly(allyl glycidyl ether),⁸⁷ poly[(methyl-2-allyloxycarbonyl-propylene carbonate)-*co*-(L-lactide)]⁸⁸ synthesized by ring-opening polymerization

Scheme 14 Synthesis of a sixth-generation dendrimer by thiol-ene (steps 1, 3, and 5) and Huisgen alkyne-azide (steps 2, 4, and 6) click reactions. [Adapted and redrawn from Ref. 53. © American Chemical Society, 2010.]

Scheme 15 Thiol–ene modification of 1,2-polybutadiene: regular addition step and intramolecular cyclization. [Redrawn from Ref. 76. © American Chemical Society, 2008.]

Scheme 16 Thiol–ene click modification of poly[2-(3-butenyl)-2-oxazoline]. [Redrawn from Ref. 84. © American Chemical Society, 2007.]

techniques, poly(octylallene-*co*-styrene) by coordination polymerization,⁸⁹ and commercial poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylene vinylene].⁹⁰

All these polymer structures have in common that the distances between double bonds are too large or backbones are too stiff to form intramolecular cycles during the radical addition process, as for poly[2-(3-butenyl)-2-oxazoline]. Evidently, the design of the polymer structure decides on the click characteristics of the thiol–ene reaction rather than the nature of the thiol or the initiation process. However, Hawker *et al.* reported that photochemical reactions yielded higher efficiencies, required shorter reaction times, and were more tolerant to functional groups and backbones than their thermal counterparts.⁸⁵

It is especially worth mentioning that the thermal addition of 2-mercaptoethanol to poly(styrene-*co*-octylallene), as described by Ni and Shen *et al.*,⁸⁹ proceeded smoothly to quantitative yield, despite the fact that the backbone contained both terminal and internal double bonds with

different reactivities. The reaction was performed in toluene solution at 70 °C (initiator: AIBN) with a 40-fold excess of thiol with respect to double bonds. Conjugated internal double bonds as in poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylene vinylene] were photochemically reacted readily with dodecanethiol in bulk ($[SH]_0/[C=C]_0 = 4$), reaching quantitative conversion within 40 s.⁹⁰

Also, poly(ethylene oxide)-*block*-poly(DL-alanyl-glycine) could be click-modified with 1-thio- β -D-glucopyranose to yield a well-defined glycopolymer without the need for protecting groups.⁸⁶ The photoaddition reaction was performed in trifluoroacetic acid as (however, not truly environmentally benign) solvent with a twofold excess of the thiosugar. Full functionalization was achieved within 2 days.

Another route toward thiol–ene “clickable” polymers is based on polymer-analog reactions, often (trans-)esterification reactions. As an example, poly(2-hydroxyethyl methacrylate)s were first reacted with 4-pentenoic acid before the addition of glucithiose (irradiation with UV light, initiator:

Figure 2 Examples of thiol-ene clickable ene polymer backbones.^{84–89}

DMPA) to yield neoglycopolymers.⁹¹ Hafrén and Córdova *et al.* modified cellulose, that is, filter paper, by tartaric acid-catalyzed reaction with either 2-(oct-7-enyl)oxirane or 9-decenoic acid to yield ene-functionalized cellulose, onto which hydrophobic thiols, for example, benzylthiol, were added in a photochemical reaction. The attachment of the thiol to cellulose could be confirmed, but not the quantitative conversion of double bonds.⁹² Huang *et al.* submitted poly(γ -benzyl-L-glutamate) to a partial transesterification reaction with allyl alcohol to obtain a poly[γ -(benzyl/allyl)-L-glutamate] copolymer.⁹³ The addition of thioglycerol to the allyl side chains ($[\text{SH}]_0/[\text{C}=\text{C}]_0/[\text{AIBN}]_0 = 40:1:2$, toluene, 80 °C, 24 hours), however, was not quantitative, which was attributed to steric hindrance and decreased reactivity of allyl groups.

Jannasch *et al.* grafted 10-undecenoyl chloride onto lithiated polysulfone followed by the thermal addition of 2-(2-benzimidazolyl)ethanethiol (Scheme 17).⁹⁴ In order to convert all double bonds into thioether links, 10 days of reaction was

required and additional amounts of AIBN were charged every 24 hours.

Thiol-ene clickable polymers may also contain thiol instead of ene groups, for instance cysteine-containing peptides (see Sections 3.1.3 and 3.1.4), poly(L-cysteine),⁹⁵ and poly[2-(2-mercaptoethyl)-2-oxazoline] copolymers,⁹⁶ as synthesized by ring-opening polymerization, and poly(pyridyl disulfide ethyl methacrylate), as synthesized by RAFT polymerization (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**) (Figure 3).^{97,98} Bulmus and Davis *et al.* investigated the exchange of the pyridyl disulfide side chain with various thiols and also glutathione; reactions were carried out at room temperature under nitrogen atmosphere to minimize the oxidation of free thiols.⁹⁷ Alternatively, but turning out to be less effective than the exchange reaction, poly(pyridyl disulfide ethyl methacrylate) was submitted to concurrent deprotection (catalyst: tris(2-carboxyethyl)phosphine) and photoaddition

Scheme 17 Thermal addition of 2-(2-benzimidazolyl)ethanethiol to undecenoyl-grafted polysulfone. [Redrawn from Ref. 94. © Elsevier, 2006.]

Figure 3 Examples of thiol–ene clickable thiol polymer backbones.^{95–97}

(UV 365 nm, DMPA) of allyl-poly(ethylene oxide) (PEO, 2 kDa) with a yield of about 60%.⁹⁸

Heise *et al.* applied radical/nucleophilic 1 : 1 additions of poly(ethylene oxide) methyl ether acrylate or fluorescein *O*-acrylate to a poly(L-cysteine) copolymer.⁹⁵ Reactions were carried out with AIBN as the initiator at 70 °C in DMF solution, in the presence of pyridine as a base, and came to completion within 1 hour.

Poly[2-(2-mercaptoethyl)-2-oxazoline] copolymers, however, have only been modified by nucleophilic but not radical thiol–ene addition.⁹⁶

It is noteworthy that free thiols on the backbone are prone to intra- and interchain thiol–disulfide exchange reactions, resulting in

nonquantitative grafting and cross-linking.^{98–100} The cysteine-containing copolymer underwent slow oxidative cross-linking under atmospheric conditions.⁹⁵ Hence, thiolated polymers are less suited for click chemistry applications than unsaturated ene polymers.

Polymers carrying carbon–carbon triple bonds in the side (or main) chains have been click-functionalized with azides, applying Huisgen [3 + 2] cycloaddition reaction, but not with thiols.

End-Functional Polymers

Polymers for thiol–ene click end-functionalization carry alkene/alkyne or thiol groups at their chain ends, which can be synthesized by living/controlled

polymerization techniques using functional initiators and/or quenching agents.^{3,101,102} Alkene/alkyne groups may and thiol groups must be appropriately protected, depending on the applied polymerization technique. Polyisobutylenes, for instance, which are available through cationic polymerization, can be readily prepared with alkene end groups. Terminal dithioester or trithiocarbonate, etc. groups of RAFT polymers can be converted into a thiol by reduction or aminolysis.¹⁰³

Poly(ethylene oxide) with terminal allyl groups (4.9 kDa)⁶⁹ or methyl(*n*)vinyl(3-*n*)silyl groups (2.8–2.9 kDa)¹⁰⁴ were quantitatively modified by thermal addition of cysteamine hydrochloride (AIBN, 15 equiv thiol, DMF, 70 °C, 24 hours) or thioglycolic acid (AIBN, 3 equiv thiol, toluene, 80 °C, 2 hours), respectively. Hawker *et al.* modified allyl-poly(ethylene oxide) (5 kDa) with various thiols (thioglycolic acid, MPTMS, thio-adamantane, Fmoc-protected cysteine, and thioglycerol) applying both thermal and photochemical procedures, the latter being the more efficient one to give quantitative

or near-quantitative (94%, thio-adamantane) conversion within 1 hour.⁸⁵ Allyl-terminated poly(ethylene oxide)-*block*-poly(L-lactide) was reacted with three model thiols, that is, 3-mercaptopropionic acid, thioglycerol, and *N*-Boc-cysteamine, in THF solution at room temperature; radicals were generated by irradiation with UV light (254 nm).⁸⁸ Reactions came to completion within 1–2 hours. Thiocholesterol could be quantitatively added to allyl-terminated poly(2-isopropyl-2-oxazoline) by irradiation with UV light.¹⁰⁵

The peroxide-initiated addition of MPTMS to the terminal methylvinylidene group of isotactic polypropylene (*i*-PP, 50 kDa) in the melt, on the other hand, failed and could only be observed in the presence of a coagent like triallyl trimellitate.¹⁰⁶ The low unsaturation content of polypropylene and the high temperature (170 °C) were shown to disfavor product formation because of the reversibility of thiyl radical attack on the olefin.¹⁰⁷

Polyisobutylene (PIB, 1.3–3.6 kDa) with one or two (α,ω -) terminal methylvinylidene groups, on the other hand, could be quantitatively

Scheme 18 Thiol–X click functionalization of polyisobutylene (PIB) carrying terminal (a) alkene. [Redrawn from Ref. 108. © Royal Society of Chemistry, 2010.] (b) Thiol → alkyne groups.¹⁰⁹

functionalized with a series of different thiols (Scheme 18a).¹⁰⁸ The thiol reactant was used at 1.5 equiv with respect to double bonds, and the reaction times were in the order of a few minutes. Also, thiol-terminated polyisobutylene (PIB) was subjected to a one-pot sequential nucleophilic thiol–ene addition of propargyl acrylate and photochemical thiol–yne addition of 6-mercaptohexanol (Scheme 18b).¹⁰⁹ Both reaction steps were confirmed by ¹H NMR spectroscopic analyses to proceed in quantitative yield.

The dithiophenyl end group of poly(*N*-isopropylacrylamide) PNIPAM (5.9 kDa), as synthesized by RAFT polymerization, was reacted with octylamine and either allyl methacrylate or propargyl acrylate in the presence of dimethylphenylphosphine, that is, *in situ* aminolysis of dithiophenyl to thiol and subsequent thiol–ene Michael addition, by Lowe *et al.*¹¹⁰ The obtained PNIPAM-alkene and PNIPAM-alkyne were then reacted with three different thiols (hexanethiol, 6-mercaptohexanol, and 3-mercaptopropyl-POSS) applying UV 365 nm light in the presence of benzil dimethyl ketal (Irgacure 651) photoinitiator, to reach quantitative conversion within 2 hours.

Termination of polystyryl lithium (2.8 kDa) with chlorodimethylsilylhydride and subsequent hydrosilylation with octavinyl-POSS yielded a PS-POSS-(vinyl)₇ (after purification by fractional precipitation).¹¹¹ After photoaddition of thioglycolic acid (DMPA, UV 365 nm, THF), the hepta carboxylated polymer was obtained in 52% yield.

Combinations of different “click” reactions have been used for the orthogonal functionalization of heterobifunctional (telechelic) polymers, for instance, α -alkene- ω -azido-polystyrene (Scheme 19a)⁸⁵ or α -alkene- ω -alkyne-poly(ϵ -caprolactone) (Scheme 19b).¹¹² In case of functionalization of alkene/azide end groups, the sequence of thiol–ene and azide–alkyne cycloaddition could be chosen arbitrarily; both pathways yielded the same product in high purity. For alkene/alkyne, the azide had to be added before the thiol because the thiol would have reacted with either end group, thereby either creating a mixture of end groups or a polymer with two functional end groups on one side and one on the other (depending on the amount of thiol employed).

It is worth noting that the click coupling or conjugation of polymer chains via radical thiol–X chemistry has been attempted, applying

both thermal and photochemical routes, but failed, especially when the reactants were employed in exact or near-equimolar ratio.¹¹³ The major side reaction causing interruption of the thiol–ene propagation circle is supposed to be the head-to-head coupling of radical leading to the formation of polymer–polymer disulfides.

3.2.2 Branched Polymers and Networks

Step-growth polymerization can be used for the creation of different architectures: linear polymers, branched polymers, and networks. First indications of the step-growth polymerization by radical thiol–ene chemistry were obtained by Braun *et al.*, who observed the formation of an extremely high-boiling material for alkene-thiols due to polymerization.^{114,115} Some time later, also the polymerization of dienes with hydrogen sulfide¹¹⁶ and dithiols were reported.^{117–120} After this initial work, especially by the group of Marvel, mostly chemical industry picked up on the thiol–ene polymerization, yielding numerous patents.¹²¹ Since the mid-1990s, thiol–ene polymerization came back into focus,^{122–132} also promoted by the works of Hoyle and Bowman.^{4,12}

Linear polymers are produced by the reaction of difunctional thiol monomers with difunctional alkene monomers or by reaction of heterofunctional thiol–alkene monomers, the latter mainly having been used in the first works because of problems with the synthesis of these monomers.¹¹⁵ The synthesis of difunctional (or multifunctional) monomers does not suffer from this disadvantage and has therefore been applied far more widely. Not only dithiols but also hydrogen sulfide can be used as difunctional monomers.¹¹⁶ By using off-stoichiometric ratios of the different monomers, the average length of the polymers can be controlled to some degree, as well as the end groups (an excess of one monomer yields polymers with such end groups). Besides purely synthetic monomers,^{117–120,133} also diene biomolecules (fatty acid-based monomers) have been used (UV, photoinitiator).^{134,135} The functional end groups can in turn be used for end-group modification (e.g., with alcohol, carboxylic acid, and silanes).^{134,135} Mostly, polymers with relatively low molecular weights up to a few kilodaltons are obtained.

Scheme 19 Orthogonal click strategy for combined radical thiol-ene addition and azide-alkyne cycloaddition: (a) alkene-polystyrene-azide. [Redrawn from Ref. 85. © American Chemical Society, 2008.] (b) Alkene-poly(ϵ -caprolactone)-alkyne. [Redrawn from Ref. 112. © Royal Society of Chemistry, 2010.]

Hyperbranched Polymers

The post-polymerization functionalization of branched polymers by radical thiol-X chemistry has also been shown. The polymers were synthesized using, for example, RAFT polymerization

Polymer Networks

Polymerization is usually initiated photo-chemically in the presence or absence of the photoinitiator. It was demonstrated that UV light with wavelengths of 254 and 365 nm can

$n = 2$  $n = 3$  $n = 4$  $n=2$  $n = 3$  $n = 4$  $n = 2$

initiate polymerization, though the initiation with the shorter wavelength was shown to be far more efficient.^{146,149}

The thiol–X radical addition proceeds exothermally, generating heat, which leads to the formation of stress in the material. It has been suggested to use the reversible addition fragmentation process to relieve this stress (Scheme 21). After polymerization, radical species are generated yielding thiyl radicals, which add to a double bond of an allyl sulfide group. The fragmentation (β -elimination) of the resulting species will favor the elimination of a strained group, thereby relieving stress.^{147,148}

The properties of the networks that are formed are strongly dependent on numerous parameters. Firstly, the nature of the monomers is highly important. The cross-linking needed for stabilization of the networks is more effective using monomers with more functional groups.¹²⁹ The resulting higher cross-linking density also results in an increase of the glass-point temperature of the materials.¹⁵⁰ Similarly, the molecular weight or size of the monomers influences the cross-linking density and thereby the glass-point temperature; lower molecular weight monomers shift the glass-point temperature to higher values. With the cross-linking density, the heat capacity of the materials also increases.¹⁵¹ The cross-linking density can also be influenced by changing the reaction conditions such as temperature and the radical concentration.¹⁵² Spacer lengths further influence properties such as the density and the free volume of the network; the use of longer spacers decreases the density of the networks and increases the free volume.¹⁵³

Since step-growth polymerization is a radical process, the free-radical polymerization of alkenes can occur, especially for (meth)acrylate monomers. At 1:1 ratio of (meth)acrylate and thiol functional groups, the degree of free-radical polymerization is minimized, though still present since the homopolymerization is faster than the thiol–ene addition.¹⁵⁴ This so-called mixed mode process allows the tuning of different properties: for instance, the

glass transition point by using an excess of alkene groups.^{150,155,156} As a side effect, phase separation can occur in the system, yielding inhomogeneous materials. The nature of the thiol hardly influences the materials properties, contrary to the alkene, though materials prepared with secondary thiols were found to be more stable upon storage.¹⁵¹

The addition of functional groups can also be used to influence the properties of the network. The addition of 3-mercaptopropionic acid to a mixture of multifunctional thiols and alkenes, for instance, yielded networks with an increased stability as a result of hydrogen-bonding interaction.¹⁵⁷

Thiol–yne chemistry, just as well as thiol–ene chemistry, can be applied to prepare networks, using multifunctional thiols and molecules with more than one triple bond. If a dithiol was to be used in combination with a monoalkyne, linear polymers should be formed, though this has not been reported yet. Radical thiol–yne chemistry yields materials with higher amounts of sulfur, thereby achieving superior refractive indices,¹⁵⁸ which makes such materials more suitable for optical applications.^{23,159} Additionally, the cross-linking density of the networks is higher.

Networks can also be prepared using a combination of methods, for example, radical thiol–X chemistry with reactions such as the nucleophilic addition of thiols to different groups (e.g., to isocyanate or epoxy groups).^{160–162} The different types of chemistry can be performed sequentially, since the nucleophilic addition requires a catalyst, whereas the radical thiol–ene addition is started upon the generation of radicals (typically by irradiation with UV light). The different reactions can also be performed simultaneously. By adjusting the reaction parameters, the properties of the final network can be controlled.

The polymer networks prepared using radical thiol–ene photopolymerization are interesting not only academically but also for applications, such as in adhesives (first commercial products are already available); as high-refractive-index,

high-energy-absorbing, and high- T_g materials; as dental restorative materials;¹⁶³ or to stabilize bone fractures.¹⁶⁴ The quick cross-linking of the monomer mixture upon irradiation with UV light as well as the tolerance of the curing toward water, oxygen, and other functional groups makes it a promising chemistry for numerous applications.

The network formation using radical thiol–X chemistry is not limited to the cross-linking of small molecular monomers, but also (end-)functionalized polymers can be used to create networks, as for instance shown for allyl end-functionalized polyurethane polymers which could be cross-linked in combination with a trifunctional thiol monomer.¹⁶⁵ Water-soluble polymers have been used in a similar way. The resulting materials can, for example, be used as hydrogels and will be discussed in the next paragraph. Besides bulk materials, also beads¹⁶⁶ (porous or nonporous, prepared using microfluidic devices) or thin layers (patterned or not) on surfaces can be prepared. The patterning of surfaces with 3D features will be discussed in Section 3.3.2.

Hydrogels

Hydrogels can be prepared using the same methods that are used to prepare thiol–ene networks. Linear, star-shaped, or branched polymers based on PEO

or PMAA with multiple functional groups, thiol, or allyl are incorporated in the network.¹⁶⁷ The reactions could be performed in bulk or in solution with solid contents ranging from 50 to 3 wt%.

Hult *et al.* prepared hydrogels based on α,ω -alkene-functionalized linear PEO in combination with three-arm star-shaped PEO–SH-bearing terminal thiol groups.¹⁶⁸ Also, the hydrogel could be covalently bound to a thiol-functionalized surface. Bowman *et al.* described the synthesis of a similar type of thiol-allyl ether photopolymers employing di- and tetrafunctional thiols and diallyl-poly(ethylene oxide).¹⁶⁹

Anseth *et al.* synthesized a series of biodegradable hydrogels based on PEO and poly(L-lactide) (PLLA) polyesters using multifunctional thiols ($n = 2, 3$, and 4) and an α,ω -diacryloyl-functionalized PLLA–PEO–PLLA triblock copolymer.^{170–172} The radical polymerization occurred in a mixed mode via chain-growth (acrylate) and step-growth mechanisms (thiol–ene), transitioning from more chain-like to more step-like with increasing thiol to acrylate ratio, thereby controlling the microstructure and degradation characteristics of the network. The conversion of the acrylate was found to be virtually quantitative, though a large number of thiol groups remained unreacted, demonstrating that thiol–ene

Scheme 22 Synthesis of peptide-based hydrogel by sequential click reactions: (a) azide-alkyne step-growth polymerization to form hydrogel and (b) thiol-ene functionalization. [Reproduced from Ref. 178. © Nature Publishing Group, 2009.]

polymerization may be efficient but is not a click reaction. It should be highlighted that the polymerization was initiated by exposure to UV light, with or without a photoinitiator, and allowed the production of centimeter-thick samples.¹⁷⁰

PEO–peptide hydrogels have also been studied by Anseth *et al.* aiming to enhance the biodegradability and to improve the binding and viability of living cells. Reactants were either a star-shaped PEO with four norbornyl end groups and a short peptide sequence bearing two cysteine moieties^{173–175} or a linear α, ω -diacryloyl–PEO and a peptide containing four cysteine residues.¹⁷⁶ It could be shown that, when proteins are encapsulated in the matrix, their activity is nearly fully maintained, showing the biocompatibility of radical thiol–ene chemistry. Another route to incorporate cysteine-containing peptide sequences into PEO hydrogels involved the mixed mode photopolymerization of PEO-diacrylate and cysteine peptide. Incorporation of about 95% peptide could be achieved at an acrylate : cysteine ratio of 4 : 1 within 10 minutes of irradiation with 365 nm light ($\sim 5 \text{ mW/cm}^{-2}$).¹⁷⁷

Anseth *et al.* have described the synthesis of a peptide-based hydrogel by Huisgen azide–alkyne [3 + 2] cycloaddition, as shown in Scheme 22.^{178,179} The pendant double bonds in the peptide sequences were then click-functionalized with thiolated dye molecules. Because the thiol–ene reaction is light-driven and the degree of modification is directly related to the dosage of light delivered to the system, it was possible to create biochemical gradients of multiple peptides with well-defined magnitude and slope throughout the 3D network.

3.3 Colloid and Surface Chemistry

Surfaces that can be functionalized with unsaturated or thiol moieties can also be used in the functionalization by radical thiol–X chemistry, though the restricted accessibility of functional groups on surfaces makes it difficult to reach quantitative conversion, as required for click chemistry. Moreover, characterization of the surface may not be easy, making it hard to prove that a certain reaction proceeded as a click reaction.

Nevertheless, any reaction that in solution is a click reaction is potentially interesting for the modification of surfaces in heterophase, where

highly efficient methodologies are needed to obtain optimal degrees of functionalization. The following part on application of radical thiol–X chemistry to surfaces is divided into the functionalization colloidal particles and of planar surfaces.

3.3.1 Modification of Colloidal Particles

Different ways to introduce unsaturated groups or thiol groups can be applied, the chemistry depending on the nature and type of the particle. For silica nanoparticles, the use of silanes is most straightforward. Acrylate-functionalized silica nanoparticles, as described by Bowman *et al.*, can be obtained using 3-acryloxypropyl trichlorosilane,¹⁸⁰ which can be converted into a thiol-terminated surface by reaction with 1,3-propanedithiol. Subsequently, 1,6-hexanedithiol and triethyleneglycol divinyl ether were photopolymerized (DMPA, UV 365 nm) to yield polymer-coated particles.

Similarly, Kang *et al.* prepared silica particles bearing methacrylate groups, which were copolymerized with *N*-vinylcarbazole in the presence of divinylbenzene.¹⁸¹ Thiol-terminated PNIPAM (prepared by RAFT, see Section 3.2.1) was added to the double bonds on the surface of particles with a grafting density of 0.1 chains/nm². The silica template was then removed by HF etching to obtain hollow polymer capsules.

Caruso *et al.* used radical thiol–ene chemistry to stabilize hydrogen-bonded multilayers of poly(*N*-vinylpyrrolidone) (PVP) and poly(methacrylic acid) bearing side chains with either thiol or acrylate groups, as prepared by layer-by-layer (LbL) deposition onto a silica particle template (Figure 5).¹⁸² After the photochemical cross-linking of the PMAA layers (256 nm, 2 hours), the silica template was removed by etching with hydrogen fluoride followed by incubation in neutral water to remove the hydrogen-bonded PVP. The obtained polymer capsules could be further functionalized by thiol–ene addition of PEO–acrylate or PEO–maleimide.

Iron oxide nanoparticles stabilized with mercaptopropionic acid¹⁸³ or 3-allylacetylacetonate¹⁸⁴ could be functionalized with charged groups, for example, but-3-ene-1,1-diylidiphosphonic acid or its ester or with cysteine. Besides inorganic nanoparticles, also fullerenes¹⁸⁵ and carbon nanotubes¹⁸⁶

Figure 5 Preparation of polymer multilayer-coated silica particles and subsequent stabilization and functionalization via thiol-ene photochemistry. [Reproduced from Ref. 182. © American Chemical Society, 2009.]

have been functionalized with aliphatic thiols by radical thiol-ene chemistry (Scheme 23).

Polymeric particles carrying double bonds were produced by emulsion polymerization of divinylbenzene.^{187,188} The functionalization of the particles with polymer chains was

performed by thermal addition of either thiol end-functionalized PNIPAM¹⁸⁷ or PEO¹⁸⁸ or by addition of 1-azidoundecan-11-thiol, which then were reacted with alkyne end-functionalized poly(2-hydroxyethyl methacrylate) (PHEMA) by azide-alkyne cycloaddition.¹⁸⁷

Scheme 23 Thiol–ene functionalization of (a) fullerenes. [Reproduced from Ref. 185. © Royal Society of Chemistry, 2010.] (b) carbon nanotubes. [Reproduced from Ref. 186. © American Chemical Society, 2009.]

Harth *et al.* showed the cross-linking of copolymers of α -allyl- δ -valerolactone and δ -valerolactone, the allyl groups of which were partially oxidized to epoxy groups with diamines.^{189,190} Cross-linking could also be performed using dithiols instead of diamines, eliminating the need for oxidation.¹⁹¹ The remaining double bonds could be functionalized with numerous different thiols, such as short peptide sequences, taxol, and dendrimers.

Schlaad *et al.* obtained porous microparticles bearing double bonds by crystallization of a statistical copolymer of poly(2-isopropyl-2-oxazoline) and poly[2-(3-butenyl)-2-oxazoline] in hot water.¹⁹² The polymer particles were functionalized in aqueous dispersion with 1-thiosugars, the conversion of double bonds reaching $\sim 60\%$. The nonquantitative addition of thiol was explained by a restricted accessibility of double bonds rather than side reactions.

Although very poorly soluble, syndiotactic 1,2-polybutadiene (PB) could be functionalized by thiol–ene chemistry either in the melt⁶¹ or in an aqueous dispersion.⁸⁰ In the latter case, the additions of 3-mercaptopropionic acid and methyl 3-mercaptopropionate proceeded to 85% yield. Using strongly hydrophilic thiols, only surface functionalization was achieved, that is, degrees of functionalization of up to 15%, nevertheless eliminating the need for surfactants in order to stabilize the dispersion.⁸⁰

Finally, Kim *et al.* synthesized nanocapsules using thiol–ene click photopolymerization of (allyloxy)₁₂cucurbit[6]uril, which is a rigid disk-shaped molecule with a cavity and 12 allyl groups at the periphery, and oligoethylene oxide or alkyl-based dithiols (Scheme 24).¹⁹³ The reaction was performed with UV radiation (254 and 300 nm) of a mixture of reactants at a ratio

Scheme 24 Template-free synthesis of polymer capsules through photopolymerization of (allyloxy)₁₂cucurbit[6]uril and dithiols. [Reproduced from Ref. 193. © American Chemical Society, 2010.]

allyloxy:thiol = 1 : 8 in methanol for 20 hours. The product was isolated in 87% yield after dialysis and contained no residual double bonds.

3.3.2 Modification of Surfaces

Polymerization on Surfaces

The formation of networks, as has been described earlier, can also be performed on surfaces. The curing of the thiol–ene mixtures can be used to make simple layers, but also to create 3D structures, using either a template (stamp) in a (nano)contact-molding imprint lithography approach^{194–199} or photomasks (Figure 6).^{200–204}

In contact-molding lithography, the material was cross-linked upon irradiation with UV light, so that the form was maintained upon removal of the template. This procedure allowed the preparation of structures with features below 100 nm. This chemistry was performed either on surfaces with functional (thiol or ene) groups, which reacted with the thiol–ene mixture (i.e., (3-acryloxypropyl)trimethoxysilane-modified silica surface, photopolymerized with di- or trifunctional enes with tetrafunctional thiol, DMPA, UV 365 nm),¹⁹⁴ or plainly on a surface (i.e., poly[(mercaptopropyl)methylsiloxane] (PMMS) with di- or trienes or using diacrylate-PEO with tetrafunctional thiols (either small molecules or PEO-based in the presence of DMPA, UV

365 nm)).¹⁹⁹ As with the networks formed in bulk, the functionality of the monomers strongly influence the stability of the features: more functional groups yield more stable layers.¹⁹⁴ The created patterns could be modified when, for instance, an excess of thiol was used in the original mixture, yielding free thiol groups on the surface of the 3D features (as shown using triene and tetrathiol monomers [SH]₀ : [C=C]₀ = 1.1, DMPA, UV 365 nm). The resulting features were either reacted with monofunctional enes (hexyl acrylate) or with the same monomer mixture as before ([SH]₀ : [C=C]₀ = 0.35). Further functionalization with monomer mixtures yielded features that were somewhat larger, thereby decreasing the minimum distance that can be reached by using contact-molding lithography alone.¹⁹⁶ A small degree of curing, before application of the template, was shown to improve the stability of the structures (commercially available thiol–ene photopolymer resist Norland Optical 60, containing tetra-ene with tri-thiol with photoinitiator, UV 365 nm).¹⁹⁷

The same principles have also been used to prepare microfluidic devices, which were shown to be very stable toward swelling by organic solvents. Devices were prepared using a polydimethylsiloxane (PDMS) template onto which a thiol–ene polymer network was cross-linked. The thiol–ene layer could be transferred either onto a planar substrate or be stacked with other layers after partial curing to create more complicated structures.^{202–204}

Figure 6 Illustration of the thiol–ene processes for making (a) stamps for contact-molding lithography. [Reproduced from Ref. 195. © Wiley-VCH Verlag GmbH & Co. KGaA, 2008.] (b) Patterned surfaces using photomasks. [Reproduced from Ref. 203. © Royal Society of Chemistry, 2008.]

Linear polymers could be polymerized on surfaces using difunctional thiols and alkenes. The (silica) substrate is functionalized with thiol groups (using MPTMS), which can be used to graft thiol–ene polymers onto (1,6-hexanediol and triethylene glycol divinyl ether, DMPA, 365-nm UV light). Any nonbound polymer could easily be rinsed away. The obtained layers were relatively thin, which suggests a low grafting density. Using combinations of photomasking (different irradiation times) and gradients in the concentration of thiol groups on the surface, gradients in the thickness of the polymer layer were achieved. Using photomasks, patterns could also be obtained since the polymerization was initiated locally.^{200,201}

Patton *et al.* performed a free-radical polymerization of poly(trimethylsilyl)propargyl methacrylate from a silica surface decorated with a photoinitiator (Figure 7a).²⁰⁵ Propargyl moieties were deprotected and subsequently functionalized

using radical thiol–yne chemistry. Though the conversion of alkyne groups was quantitative, some residual vinyl sulfide groups remained as a result of steric hindrance. The sequential polymerization of the surface could be shown: firstly a photomask was used to selectively functionalize the exposed surface, and, after removal of the mask, the rest of the surface was functionalized with a second thiol (Figure 7b).

Self-Assembled Monolayers

As with the radical thiol–ene functionalization of nanoparticles, the modification of self-assembled monolayers (SAM) requires the introduction of alkene or thiol groups onto the surface. When the goal of the reaction is the formation of a monolayer, monofunctional thiols or alkenes are used in the functionalization. Functional surfaces are very interesting for all kinds of applications, such as antifouling, lab-on-a-chip designs, and so on. The

Figure 7 (a) Illustration of the procedure of surface-initiated polymerization of propargyl methacrylate and subsequent thiol-yne modification. (b) Photopatterning of the yne polymer brush with sequential thiol-yne addition. [Reproduced from Ref. 205. © American Chemical Society, 2009.]

modular nature and the photoinitiation make radical thiol-ene chemistry a very promising tool to prepare patterned surfaces.

The functionalization of a number of surfaces has been described, including polymeric surfaces, glass and silicon oxide, hydrogen-terminated silicon, and aluminum.

Regarding polymer surfaces, poly(vinylmethylsiloxane)-based surfaces were grafted with thiolated alcohols using AIBN.²⁰⁶ Allyl-terminated polyurethane monolayers were reacted with a tetrafunctional thiol using UV light and DMPA.²⁰⁷ Subsequently, PEO-methacrylate was polymerized in a free-radical process using DMPA as a photoinitiator.

Besides silicon oxide (*vide infra*), hydrogen-terminated silicon has been functionalized through thiol-ene photochemistry.^{208,209} The Si(111) surface was first reacted with 1,13-tetradecadiene to form a C=CH₂-terminated monolayer (see **Silicon Radical Surface Chemistry**) and then exposed to 365-nm light in the presence of different thiols and DMPA

(Scheme 25).²⁰⁸ Surface coverages with thiol were found to be between 45% (cysteine) and 75% (thioglycolic acid). Also, patterned surfaces were obtained by microcontact printing (μ CP). Alternatively, the silicon surface was first coated with 1,2-polybutadiene and then functionalized with thiols by exposure to fluorescent light (first step) and UV light (second step).²⁰⁹

Alkene-terminated SAMs on silica, which can be readily prepared by using, for instance, 11-undecenyltrichlorosilane or 3-(trimethoxysilyl)propyl methacrylate, were reacted with low molecular weight thiols (i.e., *N*-acetyl-L-cysteine, dithiothreitol, 3-mercaptopropionic acid, and galactoside-thiol) or thiolated polymers, respectively.^{210,211}

Ravoo *et al.* created well-defined patterned surfaces by photochemical thiol-ene μ CP, as illustrated in Figure 8.²¹⁰ Simply, an oxidized PDMS stamp was inked with thiol and DMPA (photoinitiator), placed on an undecenyl-terminated SAM, and irradiated with high-power UV light-emitting diode

Scheme 25 Functionalization of hydrogen-terminated silicon using thiol–ene chemistry. [Reproduced from Ref. 208. © Royal Society of Chemistry, 2010.]

Figure 8 Thiol–ene microcontact printing (μCP): Placement of a thiol-inked stamp on an alkene-terminated surface and irradiation with UV light (365 nm). [Reproduced from Ref. 210. © American Chemical Society, 2010.]

(365 nm). High grafting densities could be reached within short reaction times of tens of seconds to minutes. Also, the photochemical modification of SAMs by thiol–yne chemistry was applied, but without reaching higher surface grafting densities. Evidently, the thiol addition to the surface-bound triple bonds did not proceed to completion, possibly yielding just the monoaddition product.

It is worth mentioning that, according to Jiang and Yin *et al.*, the photochemical route of grafting thiolated polymer onto a methacrylate-terminated

SAM was more efficient than the thermal route, as indicated by considerably higher grafting densities ($2.93 \mu\text{mol m}^{-2}$ vs $1.71 \mu\text{mol m}^{-2}$).²¹¹

Silicon wafers or glass slides were reacted with MPTMS to yield thiol-terminated SAMs, onto which hydrophobic alkenes (hexadecane, octadecyl vinyl ether, and octadecyl acrylate) were added by irradiation with 365-nm UV light in the presence of benzophenone as photoinitiator.²¹² Best results were obtained, however, for the coating with octadecyl acrylate in the absence of

Figure 9 Illustration of the process of patterning of thiol-terminated surfaces with ene-functionalized biotin using a laser source. [Reproduced from Ref. 216. © Wiley-VCH Verlag GmbH & Co. KGaA, 2008.]

solvent. The photochemical thiol–ene modification of MPTMS-coated glass slides, for instance with alkenes or 1,2-polybutadiene, could also be achieved in the absence of a photoinitiator.²¹³ Residual double bonds in the cross-linked polybutadiene coating could further be functionalized with, for instance, sugar thiols (thiol–ene–thiol reaction).

Bowman *et al.* prepared ultrathin thiol–ene polymer films with a thickness gradient on silicon wafers.²⁰¹ Thiol–ene films were attached to the surface by first depositing a thiol-terminated SAM and performing a thiol–ene photopolymerization reaction on the surface. Property gradients were obtained either by creating and modifying a gradient in the surface thiol density and/or by changing the polymerization conditions (exposure time to UV light through photomasks).

Just like silicon, aluminum surfaces were also coated with MPTMS and subsequently reacted with unsaturated vegetable oils.^{214,215} The thiol–ene reaction was carried out using UV light and benzophenone as photoinitiator.

Niemeyer and Waldmann *et al.* applied the thiol–ene reaction for photochemical surface patterning.²¹⁶ Thiol-terminated surfaces were prepared in a multistep procedure: polyamidoamine (PAMAM) dendrimers, which were covalently bound to the silicon oxide surface, were sequentially attached to an aminocaproic acid spacer and 2-aminoethyl disulfide; the disulfide was then

reduced to the thiol. The surface was coated with ene-functional biomolecule, that is, biotin, and either exposed to UV light through a photomask or patterned with a laser light beam ($\lambda = 411$ nm) (Figure 9). The patterns could be visualized after treatment with Cy5-labeled streptavidin by fluorescence microscopy. Later, the methodology was extended to alkene-terminated surfaces and other ene- and thiol-functionalized biomolecules (e.g., glycopeptides and oligonucleotides) and to spotting of microarrays.^{217,218}

4 CONCLUSION AND OUTLOOK

Radical thiol–ene and –yne chemistry, that is, free-radical addition of a thiol to unsaturated groups, has over the last decade developed into a powerful tool in the synthesis of numerous different materials, because it can have the characteristics of a “click” reaction, which means that it is modular, achieves high yields in a short time, is selective toward a single product, and products are easy to purify.

These characteristics are of great advantage in organic chemistry as, for instance, shown by the use of this chemistry not only in the synthesis of bioactive molecules and dendrimers but also in the synthesis and modification of macromolecules by step-growth polymerization of multifunctional enes and thiols, respectively, and the addition of thiols to macromolecules bearing unsaturated groups

(or vice versa). Another upcoming application is the modification of nanoparticles and surfaces, for which free-radical thiol–X chemistry is supremely suitable because of its high yields and especially by the ease with which patterning of surfaces can be performed by using photochemical production of free radicals.

Thiol–ene chemistry has been well established and the major progress will likely be found in even more diverse applications of chemistry, owing to the ease with which the reactions can be performed and the availability of both different functional thiols and functional enes. For the same reason, it is to be expected that the number of commercial applications of this chemistry will increase dramatically over the coming years, first ventures already having started based on the photochemical polymer network formation.

Some progress can still be made with respect to thiol–yne chemistry, which has only very recently started attracting serious attention. The fact that a single group can be functionalized with two functional thiols, in certain cases perhaps even in a distinct two-step process yielding a product with two different functional thiols, has certain advantages over thiol–ene chemistry, mainly with respect to the density of functional groups.

As already mentioned, surface modification with thiol–X chemistry has received increased interest lately. The ease with which surface patterning can be performed using photomasks, laser writing, ink-jet printing, etc., to locally generate radicals was already shown to be a promising method to create monolayers and 3D structures. Building on this proof-of-principle work, this could very easily be applied to actual systems, to be used for other sophisticated lab-on-a-chip applications, microfluidics, and so on.

Polyradicals in Batteries

Kenichi Oyaizu and Hiroyuki Nishide

Department of Applied Chemistry, Waseda University, Tokyo, Japan

1 INTRODUCTION

Batteries are composed of cathode- and anode-active materials, a separator to separate the two electrode-active materials, an electrolyte layer, and current collectors. The cathode- and anode-active materials of conventional primary and secondary batteries are usually metal oxides, such as manganese, silver, lead, nickel, and vanadium oxides, and metals such as zinc, lead, cadmium, and lithium. All the electrodes of conventional batteries are composed of metals and metal oxides (except oxygen and carbon that are used for the air battery cathode and the lithium battery anode, respectively).

Primary batteries, such as alkaline manganese and silver oxide batteries, produce electric current by a one-way chemical reaction and are not rechargeable. Portable electronic equipments, electric vehicles, and robots require rechargeable secondary batteries. At present, Li ion, lead acid, and nickel-metal hydride batteries are generally used to power them. Ubiquitous electronic devices such as integrated circuit smart cards and active radiofrequency identification tags need rechargeable batteries that are bendable or flexible and environmentally benign for durability in daily use. Designing of soft portable electronic equipments, such as rollup displays and wearable devices, also require the development of flexible batteries.

Among the secondary batteries, Li-ion batteries are becoming the most popular. Typical Li-ion battery is configured with the cathode composed of Li-ion-containing metal oxides, such as lithium

cobalt oxide, and the anode of graphite carbon. During the charging process, Li ions are eliminated from the lattice of the metal oxide cathode and intercalated into the carbon anode. During the discharging process, the cobalt oxide is regenerated by the elimination of the Li ions. Li is one of the smallest elements to yield large specific capacity ($\text{Li}_6\text{C} \rightarrow 6\text{Li}^+ + 6\text{e}^- + \text{C}$: 372 mAh g^{-1}) and the very large electromotive force (emf) generated by the Li ion ($0.5\text{C}_6\text{Li} + \text{Li}_{0.5}\text{CoO}_2 \rightleftharpoons 3\text{C} + \text{LiCoO}_2$: 3.6 V), which result in a high energy density and the highest given voltage of the battery. Another feature of the Li-ion battery is the rocking-chair-type intercalation reactions of the Li ion between the cathode- and the anode-active materials. The intercalation of Li ions into the electrodes suppresses metallic Li (dendrite) formation by separating and immobilizing each Li ion in the lattice and the layered structure. However, the intercalating diffusion of Li ions accompanied by transformation of the lattice and the layer structure during the electrode reactions results in slow kinetics and heat generation in the charging and discharging processes, often producing overheating and occasional ignition. Indeed, battery makers often issued due to overheating accidents recall of their million-scale Li-ion batteries for mobile phones and laptop computers.

Recent development of organic batteries aiming at increasing the energy density has made them promising candidates of energy-storage devices to complement the conventional inorganic-based batteries. A new trend in materials research is emerging recently, focusing on the fabrication

of organic robust radicals to allow fully reversible one-electron redox reactions featuring fast electrode kinetics and reactant cyclability.^{5–7} Nitroxide radicals such as 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) (see **Nitroxides in Synthetic Radical Chemistry**) and nitronyl nitroxides, the nitrogen radicals such as triarylammonium cation radicals, diphenylpicrylhydrazyl (DPPH) derivatives, and verdazyls, and the oxygen radicals such as phenoxyls and galvinoxyls are typically examined as the pendant group of the radical polymers (Figure 1). These radicals are persistent at ambient temperatures under air and characterized by rapid and reversible $1e^-$ electrode reactions, typically with heterogeneous electron-transfer rate constants in the order of $k_0 = 10^{-1} \text{ cm s}^{-1}$.

3 RADICAL POLYMERS FOR CHARGE TRANSPORT AND STORAGE

Radical polymers are defined as the aliphatic polymers which are highly populated with the robust radicals per repeating units. A variety of polymer backbones have been employed to bind the

radicals, such as poly(meth)acrylates, polystyrene derivatives, poly(vinyl ether)s, polyethers, and polynorbornenes (Figure 3).^{8–21} The radical sites must be bound to polymer chains because of the need to immobilize them at current collectors for exclusion of elution into electrolyte solutions that lead to discharging, to accomplish

Figure 3 Map of radical polymers showing suitability for anode- and cathode-active materials. High redox capacity is desired for high-density energy storage in batteries. Redox potential and capacity depend on the structure of the redox site and the formula weight of the repeating unit, respectively.

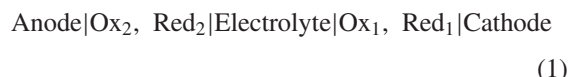

Figure 4 Charge transport and storage in radical polymers by electron self-exchange reaction throughout the polymer layer on current collectors.

appropriate mobility of the counterions, to make the electrode-active material amorphous and plasticized to accommodate deformation without heat generation, and to allow wet fabrication processes. Unpaired electron density of the polymers, determined by superconducting quantum interference device (SQUID) measurements, has revealed the presence of the radicals per repeating unit. Specific capacities based on the formula weight of the repeating unit are in the range of 50–150 mAh g⁻¹.

The unpaired electron density of the radical polymers amount to several molars in the bulk of the swollen polymer equilibrated in electrolyte solutions. Under these conditions, charge propagation within the polymer layer is sufficiently fast leading to high-density charge storage, because the redox sites are so populated that electron self-exchange reaction goes to completion within a finite distance of the polymer layer (Figure 4).^{22,23} The concentration gradient-driven charge propagation is accomplished by the electron self-exchange reaction. The exchange reaction is sufficiently fast for the diffusion-limited outer-sphere redox reactions, resulting in the efficient transfer of charge produced at the surface of the current collector. Combination of the fast electrode process ($k_0 \sim 10^{-1}$ cm s⁻¹) and self-exchange reaction ($k_{ex} \sim 10^{6-8}$ M⁻¹ s⁻¹) lead to the high rate performance of the radical battery.

4 CONFIGURATION OF RADICAL POLYMERS IN RADICAL BATTERIES

The radical polymers act as both cathode- and anode-active materials, depending on the redox potential. A couple of polymers which are different in redox potentials are used as the electroactive materials in the organic radical battery. In general, a difference in the potentials that tends to give rise to electric current is called emf. For a cell with a general configuration of

the overall reaction is $n_2 \text{Ox}_1 + n_1 \text{Red}_2 \rightleftharpoons n_2 \text{Red}_1 + n_1 \text{Ox}_2$ and the emf is given by

$$E = E_1 - E_2 = \Delta E^\circ - RT/(n_1 n_2 F) \ln \left\{ (a_{\text{Red}_1}^{n_2} a_{\text{Ox}_2}^{n_1}) / (a_{\text{Ox}_1}^{n_2} a_{\text{Red}_2}^{n_1}) \right\} \quad (2)$$

The cell voltage is $V = E - IR$ where R is the resistance of the cell. The power is $P(W) = \text{current } I(A) \times \text{cell voltage } V(V)$. In radical batteries (Figure 5), the charging process corresponds to the oxidation of the radical $\text{R}_1^\bullet$ to the cation R_1^+ at the cathode, and the reduction of the radical $\text{R}_2^\bullet$ to the anion R_2^- at the anode. The emf of the radical battery corresponds to the potential gap between the

Figure 5 Configuration of cathode- and anode-active materials in batteries, sandwiching an electrolyte layer. $R_1^\bullet$ and $R_2^\bullet$ represent the radical redox sites in the cathode- and the anode-active materials, respectively.

two redox couples according to

$$E = \Delta E^\circ - RT/F \ln\{(a_{R_1^+} a_{R_2^-}) / (a_{R_1^\bullet} a_{R_2^\bullet})\} \quad (3)$$

which typically amounts to 0.5–1.5 V. The radical polymers are reversibly converted to the corresponding polyelectrolytes during the charging process, which can be isolated and identified.²⁴

The rapid electrode reaction of the radicals and the efficient charge propagation within the polymer layer (Figure 4) lead to the excellent rate performance, allowing instant charging and large discharge currents without substantial loss of output voltages V .

The amorphous radical polymers allow fabrication of flexible thin-film devices (Figure 6). A curious feature of the radical battery is the

Figure 6 Structure and charge storage configuration of a flexible radical battery.

Figure 7 Comparison of charging curves obtained for a radical battery with that for the Li-ion battery, demonstrating the excellent rate performance of the radical battery allowing 3 s (1200 °C) full charging without loss of capacity. The radical battery composed of the PTMA cathode and the PGSt anode.

capability of burst power generation, which also allow instant full charging (i.e., in a few seconds) (Figure 7).¹⁵ Optimization of the entirely organic radical battery, typically fabricated with poly(2,2,6,6-tetramethylpiperidin-1-oxy-4-yl methacrylate) (PTMA) and poly(4-galvin-oxystyrene) (PGSt) (Figure 3) as the cathode and the anode-active materials, respectively, have allowed retention of >90% capacity even after 1000 charging/discharging cycles. Radical batteries have proved to be a new class of organic rechargeable devices, which are characterized by the rate performance and the moderate energy density. The mass-specific energy density is placed between those of polyacetylene- and disulfide-based organic batteries, but the power density is much larger and comparable to those of supercapacitors.

Figure 8 Prototype of the radical battery using a radical polymer as the cathode-active material. Ethyl carbonate–diethyl carbonate (EC/DEC) containing LiPF_6 is the most typically used as the electrolyte.

5 TECHNOLOGICAL TRENDS OF RADICAL BATTERIES DESIGNED FOR PRACTICAL APPLICATION

The radical battery is being developed for sub-battery and smart card applications.^{25–28} Because of their high-power characteristics, radical batteries in a compact battery pack are expected to power a desktop computer as a sub-battery for emergency use. Their environmentally benign properties are suitable for powering smart cards. A 100 mA h-class aluminum-laminated-film-packaged radical battery with the PTMA/carbon cathode²⁹ and a graphite anode has been fabricated (Figure 8). The composite electrode consists of 50 wt% PTMA and 45 wt% vapor-grown carbon fiber (VGCF). The composite electrode and graphite anode are 180- and 20- μm thick, respectively. The electrode is $45 \times 55 \text{ mm}^2$, which is half of a business card. The fabricated battery weighs 22 g and is 4.3-mm thick. A battery pack consisting of four such batteries connected in series operated a 200-W-class desktop computer without additional power input, so the battery is suitable for emergency use as a sub-battery. The battery pack is sufficiently compact to install in an expansion slot of a desktop computer. A rate capability test has demonstrated that the battery pack has a 13 A (130C-rate) discharge, although the capacity decrease to half that at a lower rate. Organic radical batteries could also be used as high-power energy sources, such as sub-batteries for electronic devices and motor assistance for electric vehicles, replacing the electric double-layer capacitors and nickel metal hydride batteries.²⁵

Thin organic radical batteries are being developed for application to smart cards. A prototype

Figure 9 Prototype of the thin and flexible radical battery (NEC Co.) loaded on flash devices and smart cards.

battery with a thickness of $800\mu\text{m}$ has been fabricated and tested, which is composed of a composite electrode containing 70 wt% poly(2,2,6,6-tetramethylpiperidin-1-oxy-4-yl vinyl ether) (PTVE) and a lithium metal anode. The electrode is $24 \times 22\text{ mm}^2$. The discharge capacity of the battery is 6.0 mA h. The I - V characteristics have been investigated using the 1-s pulse discharge method. The direct current resistance of the battery is only 1.5Ω , and the maximum power output is 2.0 W. This output power is sufficient for high-power applications such as for the luminescence of a flash device using light emitting diode (LED). The prototype battery embedded in a smart card is shown in Figure 9.^{30,31}

The pulse cyclability of the battery was examined by subjecting it to 5 mA (5 s) pulse discharges once a minute. Almost no deterioration was observed up to 10 000 pulse cycles even at 40°C . This stability further supports the practical application of the organic radical battery.²⁵

Efforts have been directed toward further increasing the theoretical energy density of the radical batteries. For this purpose, various radical polymers with even smaller formula weights per repeating unit are under development.

6 CONCLUSION AND OUTLOOK

Radical polymers are emerging as a new class of organic electrode-active materials, taking advantage of their unique charging/discharging processes allowing instant charging and excellent power rate capabilities. The electrochemical reversibility is considered a pervasive characteristic of organic robust radicals. Charging and discharging of the radical polymer layers are accomplished by the reversible $1e^-$ self-exchange reaction

between the neighboring sites to allow a redox-gradient-driven charge propagation throughout the polymer layer. The use of the radical polymers has offered design principles to explore the rechargeability of organic materials which are useful for various wet-type electronic devices such as batteries, solar cells, sensors, and electrochromic displays. It may also be added that the inherent environmentally benign properties are also advantageous for a sustainable development, based on the rare metal free, safe, and disposable features of the radical polymers.

Radical Chemistry on Fullerenes

Manolis D. Tzirakis and Michael Orfanopoulos

University of Crete, Department of Chemistry, Crete, Greece

1 INTRODUCTION

Free-radical reactions were one of the first investigated reactions of fullerene C_{60} .^{1–3} Since this molecule has 30 carbon–carbon double bonds, multiple additions of a variety of radicals can take place very readily, which typically results in a complex and thus difficult-to-separate mixture of products. For example, up to 11 phenyl groups, 15 benzyl groups, and 34 methyl groups have been reported to add to C_{60} .^{4,5} Owing to this property, C_{60} has been characterized as a “radical sponge”.^{4,5} On the other hand, thorough studies in the field of fullerenes’ radical chemistry have led to the development of appropriate reaction protocols that allow the selective preparation of monoaddition fullerene adducts or multiadducts with well-defined addition pattern. In addition, electron spin resonance (ESR) spectroscopic studies have provided valuable insight into the basic characteristics of the radical reactions of fullerenes, including the reactivity of radicals of various chemical nature (i.e., alkyl, perfluoroalkyl, O-, S-, P-, B-, Pt-, and Si-centered radicals) with respect to C_{60} and C_{70} , the delocalization of the unpaired electron in monofullerenyl radicals ($RC_{60}^{\bullet}$ and $RC_{70}^{\bullet}$), and their reactivity.^{1,4–30} The aim of this article is to provide a concise review of both the fundamentals and practical synthetic applications of fullerenes’ radical chemistry.

2 ADDITION OF C-CENTERED RADICALS

The addition of alkyl radicals $R^{\bullet}$ ($R = \textit{tert}$ -butyl, 1-adamantyl, isopropyl, ethyl, benzyl) to C_{60} was

among the first reactions to be studied.⁶ Initially, it was found that the unpaired electron in the resulting $RC_{60}^{\bullet}$ radical adducts is essentially confined to the three carbon atoms ortho (C1, C5, C5') and the two carbon atoms para (C3, C3') to the point of attachment of R (Figure 1), which rules out an extensive delocalization of the unpaired electron over the C_{60} sphere.^{6,7} Further studies led to a reassignment of the density of the unpaired spin; the highest spin density was found for C1, whereas almost no spin density was found on C5 and C5', which leads to only two major canonical resonance structures of $RC_{60}^{\bullet}$.^{13,27}

An important feature of fullereryl radicals is the hindered rotation about the $R-C_{60}^{\bullet}$ bond, so that the alkyl groups adopt preferred conformations relative to the C_{60} framework.^{1,8,11,14,18,27,31} For example, the $CH_3CH_2C_{60}^{\bullet}$ radical adopts asymmetrical equilibrium conformation, that is the terminal methyl group moiety is placed directly above one of the two 6-membered fused rings of C_{60} ,¹¹ whereas the terminal CF_3 group in $CF_3CH_2C_{60}^{\bullet}$ prefers the position above a pentagon (Figure 2a,b).^{19,21,27} It has been typically shown that in radicals of the general type $XYZCC_{60}^{\bullet}$, where X, Y, and Z are CF_3 , F, H, or CH_3 , a CH_3 group will never gain the pentagon position except when there is no alternative [i.e., $(CH_3)_3CC_{60}^{\bullet}$, Figure 2c], whereas a CF_3 group will never gain the hexagon(s) position except when there is no alternative [i.e., $(CF_3)_3CC_{60}^{\bullet}$].^{21,27}

A remarkable feature of the ESR spectra of a series of $RC_{60}^{\bullet}$ radicals is the increase in intensity of the spectrum with increasing temperature, which indicates that the fullereryl radicals are in an equilibrium with their diamagnetic dimers.^{7,8,22,25,31,32}

Figure 1 Atom numbering in the pyracylene unit of $\text{RC}_{60}^{\bullet}$ radicals.

Figure 2 Preferred conformation of (a) $\text{CH}_3\text{CH}_2\text{C}_{60}^{\bullet}$, (b) $\text{CF}_3\text{CH}_2\text{C}_{60}^{\bullet}$, and (c) $(\text{CH}_3)_3\text{CC}_{60}^{\bullet}$ radicals.

The dimer bond strength depends strongly on the size of R, suggesting that bonding in the dimer is greatly influenced by steric effects.⁸ Molecular graphics calculations as well as experimental results suggest that the dimerization of the fullereryl radicals follows the “head-to-head” rather than the “head-to-tail” type and involves the C3 or C3' atoms, whereas steric hindrance prevents the dimerization at C1 atom (Figure 1).^{7,8} The tendency of fullereryl radicals for dimerization has led to

the development of appropriate protocols for the synthesis of singly bonded C_{60} dimers.^{33,34} The alkylfullerene dimers have very weak C–C bond energies, and can be photolytically cleaved into alkylfullerene radicals by excitation at 532 nm.²⁹

Prolonged irradiation of C_{60} solutions in the presence of excess radical precursors leads to multiple radical additions, as indicated by line broadening in the ESR spectra and by mass spectroscopy.^{1,4,5,31,35} For example, it has been shown that photochemically generated benzyl radicals react with C_{60} producing radical and nonradical adducts R_nC_{60} ($\text{R} = \text{C}_6\text{H}_5\text{CH}_2$) with $n = 1$ to at least 15.⁵ The radical adducts with $n = 3$ and $n = 5$ have been identified by ESR spectroscopy as the allylic radical $\text{R}_3\text{C}_{60}^{\bullet}$ (**3**) and cyclopentadienyl radical $\text{R}_5\text{C}_{60}^{\bullet}$ (**5**) (Scheme 1). The unpaired electrons were found to be highly localized on the C_{60} surface. The extraordinary stability of radicals **3** and **5** was attributed to the steric protection by three or five benzyl substituents, respectively, sheltering the surface radical sites.⁵ The initially formed radical $\text{RC}_{60}^{\bullet}$ (**1**) is probably a short-lived species and it is consumed by reaction with $\text{R}^{\bullet}$ continuously generated by photolysis.⁵ The reaction pathway leading to **3** and **5** in Scheme 1 is the result of a radical addition or coupling in a way that minimizes both steric hindrance and [5,6] double bonds.⁵ Similarly, photochemically generated methyl radicals add readily to C_{60} to afford $(\text{CH}_3)_n\text{C}_{60}$ with $n = 1$ to at least 34, as evidenced by mass spectrometric analyses.⁵

Scheme 1 Stepwise addition of five benzyl radicals $\text{R}^{\bullet}$ to C_{60} .

The use of dimer $[(\text{FC}_6\text{H}_4)\text{C}(\text{CF}_3)_2]_2$ as a radical precursor allowed the observation of a step-by-step multiaddition of benzyl radicals to C_{60} .^{1,35} The addition was performed upon dissociation of the dimer in a C_{60} -saturated toluene solution at 310 K, and the reaction was monitored by EPR and mass spectrometry.³⁵ In the case of the 3,5-dimethylphenylmethyl radicals, the fifth radical does not add, probably because of steric hindrances caused by its large size compared to that of the benzyl radical.³⁵

The rate constants for the addition of various carbon-centered radicals to fullerene have been determined with the help of laser flash photolysis and competitive addition of free radicals to spin traps.^{36,37} These rate constants are two orders of magnitude higher than those for the addition of radicals to a wide class of monosubstituted unsaturated compounds.^{1,36,37}

Unlike C_{60} in which all 60 carbon atoms are equivalent, C_{70} contains five types of carbon atoms and thus five regioisomeric radical monoadducts $\text{RC}_{70}^\bullet$ are possible.^{1,24,38} ESR studies on the addition of several photochemically generated aryl and fluoroalkyl radicals to fullerene C_{70} showed that, while simple alkyl radicals afford only three of the five expected $\text{RC}_{70}^\bullet$ regioisomers, the more reactive aryl and fluoroalkyl radicals give rise to four, whereas the $^\bullet\text{CF}_3$ and $\text{CH}_3\text{O}^\bullet$ radicals yielded the ESR spectra of all five expected isomers.^{24,25}

2.1 Radical Reactions of C_{60} Mediated by Decatungstate ($\text{W}_{10}\text{O}_{32}^{4-}$)

The use of tetrabutylammonium decatungstate [TBADT, $(n\text{-Bu}_4\text{N})_4\text{W}_{10}\text{O}_{32}$] catalysis³⁹ in nano-carbon functionalization chemistry can be regarded as a new, convenient, and highly efficient strategy for C–C bond formation in fullerenes.^{40–43} This

method has enabled the otherwise inaccessible chemical modification of [60]fullerene with a great variety of organic substrates, including toluenes, anisoles and thioanisole,⁴⁰ aldehydes,⁴¹ ethers, sulfides,⁴² and alcohols.⁴³

2.1.1 Addition of Benzyl, Phenoxymethyl, and Phenylthiomethyl Radicals

Decatungstate was recently found to promote the generation of carbon-centered radicals by activating the methyl C–H bond in a series of substituted toluenes, anisoles, and thioanisole.⁴⁰ The so-obtained radical intermediates can be successfully trapped by C_{60} to afford selectively the corresponding monofunctionalized fullerene adducts in moderate to good yields (Scheme 2). The observed single addition of radicals to C_{60} is of particular interest, given the well-established high affinity of C_{60} —a “radical sponge”—with free radicals, which results in multiple radical additions.⁵ For example, up to 15 benzyl groups have been reported to add to C_{60} .⁵ Apart from the synthetic applications of this reaction, a mechanistic approach has also been provided in which a hydrogen atom abstraction from the CH_3 or the CH_3O group occurs in the rate-determining step of the reaction. The formation of the [60]fullerene radical anion ($\text{C}_{60}^{\bullet-}$) has been proposed as one of the key intermediates of this reaction.

2.1.2 Addition of Acyl Radicals

Recently, a convenient and highly efficient photochemical methodology for the direct acylation of C_{60} has been developed.⁴¹ This method includes the reaction between C_{60} and a wide variety

Scheme 2 TBADT-mediated radical reaction of *para*-substituted toluenes and anisoles with C_{60} .

Scheme 3 TBADT-mediated radical addition of aldehydes to C_{60} .

of acyl radicals derived from the corresponding aldehydes through a hydrogen atom abstraction process mediated by TBADT³⁹ (see **Synthetic Radical Photochemistry**) (Scheme 3).⁴¹ Thus, the preparation of a novel class of fullerene-based materials, namely acylated fullerene monoadducts, has been achieved in moderate to good yields.⁴¹ Moreover, a simple, low-temperature approach has been established for overcoming decarbonylations encountered in certain acyl radical addition reactions where the acyl radical intermediates are prone to undergo rapid decarbonylation, such as in the case of phenylacetaldehyde where the decarbonylation rate constant is high ($k_d > 10^6 \text{ s}^{-1}$).⁴¹ Intra- and intermolecular deuterium isotope effect studies showed a rate-determining C–H(D) bond breaking in the transition state of the first slow carbonyl radical-forming step.⁴¹ The so-obtained acylated fullerenes have been shown to be excellent $C_{60}H_2$ precursors, since they can be quantitatively converted into the simplest [60]fullerene hydride $C_{60}H_2$, upon a simple treatment with basic Al_2O_3 .⁴⁴

2.1.3 Addition of α -Hydroxyl- or α -Oxy-alkyl radicals

Recently, a facile free-radical route toward the direct functionalization of fullerene C_{60} with ethers and thioethers has been developed.⁴² The otherwise unreactive α -C–H bond in a series of structurally diverse mono- or polyethers and sulfides was achieved via decatungstate catalysis. This method enables direct access to the simplest [60]fullerene/crown ether conjugates that possess great potential as building blocks in supramolecular materials science (Scheme 4).⁴²

Tetrahydrofuranyl radicals have been also added to C_{60} by the reaction of [60]fullerene with an arylzinc halide in a mixture of tetrahydrofuran (THF) and dimethylformamide (DMF). This reaction

produces a mono(2-tetrahydrofuranyl) adduct of C_{60} [$C_{60}(C_4H_7O)H$] in good yield. On the other hand, in the presence of a copper(I) complex, the aryl group of the zinc reagent add four times regioselectively to the mono(2-tetrahydrofuranyl) adduct to produce a penta-adduct $C_{60}Ar_4(C_4H_7O)H$ (Scheme 5).⁴⁵

Recently, a general method for the selective, and yet direct, mono-hydroxyalkylation of C_{60} has been developed (Scheme 6).⁴³ This method includes the reaction of C_{60} with α -hydroxy C-centered radicals derived from commercially available alcohols upon decatungstate photocatalysis. In this way, the otherwise inaccessible mono-hydroxyalkylated fullerene derivatives are selectively obtained in moderate yields (Scheme 6).⁴³

2.2 Radical Reactions of C_{60} Mediated by $Mn(OAc)_3$, $Fe(ClO_4)_3$, $Cu(OAc)_2 \cdot H_2O$

In 2003, Wang *et al.* reported the first free-radical reaction of [60]fullerene promoted by manganese(III) acetate dihydrate [$Mn(OAc)_3 \cdot 2H_2O$] (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**).⁴⁶ In this study, free radicals were generated from various active methylene compounds (i.e., dialkyl malonates). In particular, a hydrogen atom abstraction from β -diesters by $Mn(OAc)_3 \cdot 2H_2O$, in refluxing chlorobenzene, afforded C-centered radicals which reacted with [60]fullerene to give singly bonded fullerene dimers and 1,4-bisadducts (Scheme 7). When a bromo-substituted β -diester was used, this reaction afforded the corresponding 1,4- and 1,16-bisadducts as shown in Scheme 7.

On the other hand, when cyano-substituted active methylene compounds were used, cyclopropane-fused C_{60} derivatives were exclusively obtained (Scheme 8).

Scheme 4 TBADT-mediated radical reactions of C_{60} with ethers and sulfides.

Scheme 5 Addition of tetrahydrofuran to C_{60} through arylzinc halide induced C-H bond activation.

Scheme 6 TBADT-mediated radical addition of alcohols to C_{60} . [Ref. 43 - Reproduced by permission of The Royal Society of Chemistry. <http://dx.doi.org/10.1039/C0CC02836C>.]

The same $Mn(OAc)_3$ -promoted reaction of C_{60} with substituted malonate esters or ethyl cyanoacetate in refluxing toluene gave the corresponding benzyl-substituted unsymmetrical 1,4-adducts of C_{60} , where the benzyl substituent comes from the reaction solvent (Scheme 9).⁴⁷

In order to avoid the participation of toluene in the reaction outcome, Wang *et al.* recently studied the $Mn(OAc)_3$ -mediated reaction of C_{60} with diethyl methylmalonate in an alternative solvent, namely *o*-dichlorobenzene, at 140 °C.⁴⁸ The major products of this reaction included the corresponding

Scheme 7 $\text{Mn}(\text{OAc})_3$ -mediated reaction of C_{60} with malonate esters or diethyl bromomalonate.

Scheme 8 $\text{Mn}(\text{OAc})_3$ -mediated reaction of C_{60} with malonodinitrile and ethyl cyanoacetate. [Ref. 46 - Reproduced by permission of The Royal Society of Chemistry. <http://dx.doi.org/10.1039/B309939C>.]

Scheme 9 $\text{Mn}(\text{OAc})_3$ -mediated reaction of C_{60} with substituted malonates or ethyl cyanoacetate in refluxing toluene.

1,4- and 1,16-adducts of C_{60} along with a disubstituted C_{60} -fused γ -lactone. The presence of dimethylaminopyridine (DMAP) in this reaction decreased the yield of the disubstituted C_{60} -fused γ -lactone. The selectivity of this reaction was, however, very poor to find further applications in fullerene chemistry. The selectivity toward the desired disubstituted C_{60} -fused γ -lactone was greatly improved when ferric perchlorate $[\text{Fe}(\text{ClO}_4)_3]$ instead of

$\text{Mn}(\text{OAc})_3$ was used as the reaction catalyst in the presence of acetic anhydride. Thus, the $\text{Fe}(\text{ClO}_4)_3$ -mediated reaction of substituted malonate esters with C_{60} afforded the rare disubstituted [60]fullerene-fused lactones (Scheme 10).⁴⁸

This study was complementary to previously reported studies by Wang *et al.*, where a series of novel [60]fullerene-fused lactones had been prepared by the $\text{Mn}(\text{OAc})_3 \cdot 2\text{H}_2\text{O}$ -mediated reaction of

Scheme 10 Fe(ClO₄)₃- and Mn(OAc)₃-mediated radical reactions leading to mono- and disubstituted C₆₀-fused lactones.

C₆₀ with carboxylic acids, carboxylic anhydrides, or malonic acids (Scheme 10).^{49–51} The majority of these C₆₀-fused γ-lactones were monosubstituted lactones. The only disubstituted C₆₀-fused γ-lactone that had been reported in these studies had been formed from the Mn(OAc)₃-mediated reaction of C₆₀ with isobutyric acid.⁵⁰ However, the desired C₆₀-fused γ-lactone was a minor product since the concurrent formation of a fullereryl ester originating from the facile generation of a secondary radical via decarboxylation from isobutyric acid predominated. The so-obtained C₆₀-fused lactones could undergo further transformations to afford reductive ring-opening products,⁴⁹ fullerene hemiketals and hemiacetals, fullerenols, and C₆₀-fused dihydrofurans.⁵²

Interestingly, Wang *et al.* showed that the lead(IV) acetate-promoted radical reaction of [60]fullerene with carboxylic acids, including those mentioned above for the construction of C₆₀-fused γ-lactones, gave selectively another type of fullerene products, namely fullereryl esters (Scheme 11).⁵⁰

Similarly, Gao and coworkers have systematically studied the free-radical reactions of some β-dicarbonyl compounds (i.e., malonate esters, β-keto esters, and β-diketones) in chlorobenzene and/or toluene with [60]fullerene in the presence of manganese(III) acetate dihydrate

[Mn(OAc)₃·2H₂O].⁵³ These substrates showed different tendencies to generate dihydrofuran-fused [60]fullerene derivatives or 1,4-bisadducts. In particular, dihydrofuran-fused C₆₀ derivatives could be formed by treatment of α-unsubstituted β-diketones or β-ketoesters with [60]fullerene in refluxing chlorobenzene (Scheme 12). On the other hand, solvent-participated unsymmetrical 1,4-bisadducts were obtained through the reaction of [60]fullerene with dimethyl malonate or α-substituted β-dicarbonyl compounds in toluene (Scheme 12),⁵³ as has been similarly observed by Wang *et al.* (i.e., for substituted malonates, see Scheme 9).⁴⁷

Similar results on the reaction of β-diketones and β-keto esters with C₆₀ in the presence of Mn(OAc)₃·2H₂O have been independently reported by Wang *et al.*⁵⁴ In this study, the addition of 4-dimethylaminopyridine (DMAP) allowed lower reaction temperatures (80 °C), shorter reaction times, and usually higher product yields for the corresponding C₆₀-fused dihydrofuran derivatives.⁵⁴ Moreover, it was found that the copper(II) acetate monohydrate Cu(OAc)₂·H₂O could replace manganese(III) acetate dihydrate Mn(OAc)₃·2H₂O in these radical reactions of C₆₀. On the other hand, the reaction of C₆₀ with aromatic methyl ketones, under similar conditions, gave two different products, namely

Scheme 11 Pb(OAc)₄-promoted radical reaction of C₆₀ with carboxylic acids.

Scheme 12 Selected radical reactions of C_{60} mediated by $Mn(OAc)_3$.

methanofullerenes and dihydrofuran-fused C_{60} derivatives (Scheme 12). In this latter reaction, $Cu(OAc)_2 \cdot H_2O$ was found to favor the formation of methanofullerenes.⁵⁴

Dihydrofuran-fused C_{60} derivatives have been also prepared through solvent-free reactions of 1,3-cyclohexanedione, 5,5-dimethyl-1,3-cyclohexanedione, 2,4-pentanedione, and ethyl acetoacetate with C_{60} in the presence of $Mn(OAc)_3 \cdot 2H_2O$ and ceric ammonium nitrate (CAN) under the high-speed vibration milling (HSVM) conditions.⁵⁵ CAN was found to be a better oxidant than $Mn(OAc)_3 \cdot 2H_2O$ in these mechanochemical reactions of β -dicarbonyl compounds with C_{60} .

Finally, manganese(III) acetate $Mn(OAc)_3 \cdot 2H_2O$ has been also reported to catalyze the radical reaction of [60]fullerene with β -enamino carbonyl compounds.⁵⁶ The major products obtained in this reaction are C_{60} -fused pyrroline derivatives whose nitrogen atom is directly connected to the fullerene cage (Scheme 12).

2.3 Addition of Fluoroalkyl Radicals to C_{60}

Fluoroalkyl groups (R_F) are known to add to C_{60} via a radical mechanism.^{18–21,31} Perfluoroalkylation of C_{60} is among the most thoroughly studied radical reaction of [60]fullerene resulting in a plethora of new compounds, mostly polyadducts, with interesting addition patterns and physico-chemical properties. Initially, perfluoroalkylated derivatives of C_{60} were prepared by thermal or photochemical decomposition of fluoroalkyl iodides or fluorodiacyl peroxides.^{31,57} Then, 1-fluoroalkyl-1,2-dihydro[60]fullerenes ($R_F C_{60}H$) were prepared by the reaction of C_{60} with fluoroalkyl halides ($R_F X$) in the presence of Bu_3SnH [$R_F = CF_2CO_2Et$, $n-C_6F_{13}$, CF_2Br , $n-C_{12}F_{25}$, $(CF_2)_6I$].⁵⁸ Photolysis of alkyl-mercury compounds $[Hg(R_F)_2]$,^{1,59} or the high-temperature reaction of C_{60} or C_{70} with $R_F I$,^{60–66} provides also another route toward fluoroalkyl radical addition to fullerenes.

Trifluoromethylation of [60]fullerene is the most widely studied reaction of C_{60} with fluoroalkyl

radicals and is still an area of ongoing research interest.^{67–80} Similar to other perfluoroalkyl radicals mentioned above, trifluoromethyl radicals have been typically prepared by thermal decomposition of metal trifluoroacetates $[(CF_3CO_2)_nM, M = Ag, Hg, Cu, Pd, Cr]$ ^{68–71,76,79} and pyrolysis of trifluoromethyl iodide.^{72–75,77,80} Analogous methods were used for the preparation of trifluoromethylated C_{70} ,^{72,79,81–89} higher fullerenes,^{90–98} and aza[60]fullerene.⁹⁸ Variations in the conditions of these methods (e.g., nature of the perfluoroalkyl radical precursor, temperature, pressure, reaction medium, duration) allowed the preparation of variegated trifluoromethylated fullerene adducts. The majority of these reactions were shown to be nonselective and, with some exceptions,^{73,99} the separation of the product mixture into pure isomers is either difficult or impossible. On the other hand, derivatization, such as trifluoromethylation, provides an expedient route toward the structural characterization (i.e., cage connectivity) of higher fullerenes (e.g., C_{74} , C_{76} , C_{78} , C_{84} , C_{88} , C_{92} , C_{94} , C_{96})^{90,92–97} because of the easier separation of their trifluoromethylated derivatives. Cycloperfluoroalkyl adducts of fullerenes have been also prepared through the addition reaction of biradicals thermally generated from terminal diiodoperfluoroalkanes $I(CF_2)_nI$ to C_{70} or C_{60} .^{100,101}

Fluoroalkyl radical addition to C_{60} has been well studied mainly by ESR spectroscopy.^{18–21,27,31}

As with alkyl radical additions, fluoroalkyl monoadducts exhibited a hindered rotation about the R_F-C_{60} bond and a tendency for dimerization. For example, the photochemical addition of perfluoroalkyl radicals [derived upon photolysis of perfluoroalkyl iodides in the presence of $(R_3Sn)_2$] to C_{60} , afforded the corresponding fullerene dimers in good yields.³³

2.4 Other Reactions of C_{60} Involving C-Centered Radicals

Alkyl radicals have been also prepared by photolysis of 2,2'-azo(bisisobutyronitrile) (AIBN).^{102,103} For example, Ford *et al.* have shown that the thermal decomposition of AIBN in a 1,2-dichlorobenzene solution of C_{60} generates 2-cyano-2-propyl radicals which add to C_{60} to afford three regioisomeric fullerene adducts, namely the 1,2-, 1,4-, and 1,16-isomers (Scheme 13).^{103,104} On the other hand, thermal decomposition of dimethyl azo(bisisobutyrate) (DMAIB) in the presence of C_{60} produced only the corresponding 1,4- and 1,16-isomers (Scheme 13).¹⁰³

Another C-centered radical addition to C_{60} involves the addition of aryl radicals derived from phenylhydrazines (Scheme 14).¹⁰⁵ In particular, Wang and coworkers have found that

Scheme 13 Radical reaction of C_{60} with azo(bisisobutyronitrile) and azo(bisisobutyrate).

Scheme 14 One-pot sequential synthesis of acetoxylation C_{60} derivatives.

the reaction of [60]fullerene with 4-substituted phenylhydrazine hydrochlorides in refluxing chlorobenzene under aerobic conditions affords 1-aryl-1,2-dihydro[60]fullerenes (ArC_{60}H), which are subsequently oxidized to 1-acetoxyl-4-aryl-1,4-dihydro[60]fullerenes ($\text{ArC}_{60}\text{-OAc}$) by $\text{Mn}(\text{OAc})_3 \cdot 2\text{H}_2\text{O}$ in a one-pot procedure (Scheme 14).¹⁰⁵ The formation of the final adduct was rationalized through the radical addition to C_{60} of aryl radicals generated *in situ* from the phenylhydrazine derivative by oxidation via oxygen, followed by radical coupling with $\text{H}^\bullet$ and subsequent oxidation by $\text{Mn}(\text{OAc})_3 \cdot 2\text{H}_2\text{O}$ (Scheme 14).

Upon the addition of sodium nitrite (NaNO_2) in the presence of O_2 and moisture, the above reaction afforded fullereneols of the type 1,4- C_{60}ArOH (Scheme 15).¹⁰⁶ The first step of this reaction involves again the addition of $\text{Ar}^\bullet$ radicals to C_{60} .

C-centered biradicals have been also employed in fullerene radical functionalization chemistry. For example, Ohno *et al.* have shown that the cycloaddition reaction of C_{60} with 3,4-fused pyrrolo-3-sulfolenes affords, after SO_2 extrusion, a C_{60} -pyrrole derivative (Scheme 16).¹⁰⁷ The proposed reaction mechanism involves the trapping of an intermediate diradical with a fullerene double bond (Scheme 16).¹⁰⁷

Scheme 15 Reaction of C_{60} with 4-substituted phenylhydrazine hydrochlorides and NaNO_2 .

Scheme 16 Cycloaddition of C_{60} with 3,4-fused pyrrolo-3-sulfolenes.

The construction of fullerene-based polymers is another research field where the addition of C-centered radicals to C_{60} is a key feature. The usual radical polymerization methods for the construction of PS-C_{60} (polystyrene- C_{60}) adducts produce, in most cases, a mixture of poorly defined multiadducts of PS. In order to control radical polymerization with C_{60} , a “living” radical polymerization has been developed which includes the reaction of 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO)-terminated polystyrene with C_{60} .¹⁰⁸ Living radical polymerization (see **Fundamentals of Controlled/Living Radical Polymerization**) has led to the synthesis of well-defined disubstituted polymer derivatives of C_{60} .^{108,109} The first example included the thermolysis of TEMPO-PS adducts in the presence of excess C_{60} in *o*-dichlorobenzene to afford the corresponding 1,4-disubstituted derivatives of C_{60} in good yields (Scheme 17).¹⁰⁸ Bromo-terminated polymers, including bromo-terminated polystyrene, have been also added to C_{60} through an atom transfer radical polymerization (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**).¹¹⁰ Several other free-radical mediated polymerizations with C_{60} have been reported in the literature.¹¹¹

3 O- AND S-CENTERED RADICALS

Several alkoxy ($\text{RO}^\bullet$) and alkylthio ($\text{RS}^\bullet$) radicals are known to add to C_{60} or C_{70} sphere affording the corresponding $\text{RO-C}_{60}^\bullet$ ($\text{RO-C}_{70}^\bullet$) and $\text{RS-C}_{60}^\bullet$ ($\text{RS-C}_{70}^\bullet$) radical adducts which can be detected by ESR spectroscopy.^{15,25,112} Alkoxy radicals ($\text{RO}^\bullet$) have been generated photolytically from the appropriate peroxides ROOR ($\text{R} = t\text{-Bu}, \text{PhCMe}_2, \text{CF}_3$)¹⁵ or in a more convenient and safer way via photolysis of dialkoxy disulfides ROSSOR ($\text{R} = \text{Me}, \text{Et}, i\text{-Pr}, t\text{-Bu}, i\text{-PrCH}_2, t\text{-BuCH}_2$)

Scheme 17 Synthesis of 1,4-dipolystyryldihydro[60]fullerenes. [Reprinted with permission from Ref. 108. Copyright 1997 American Chemical Society.]

Scheme 18 Addition of alkoxy radicals to C_{60} .

(Scheme 18),^{25,112} whereas bis(alkylthio)mercury compounds (RSHgSR) and alkyl disulfides (RSSR) have been used as the source of the alkylthio radicals ($\text{RS}^{\bullet}$) (Scheme 19).^{15,25} One regioisomer is expected for the single addition radical adducts $\text{RO-C}_{60}^{\bullet}$ (Scheme 18) and $\text{RS-C}_{60}^{\bullet}$ (Scheme 19).

On the other hand, three regioisomers of $\text{MeS-C}_{70}^{\bullet}$ adduct were obtained by photolysis of dimethyl disulfide (MeSSMe) in the presence of C_{70} , whereas all the five expected regioisomers of $\text{MeO-C}_{70}^{\bullet}$ could be detected by ESR spectroscopy, upon photolysis of MeOSSOMe in the presence of C_{70} .²⁵

Unlike the spectra of $\text{RC}_{60}^{\bullet}$ radicals, which typically become more intense at higher temperatures

owing to the dissociation of $\text{RC}_{60}\text{-C}_{60}\text{R}$ dimers present in solution,⁷ the signal intensities in the ESR spectrum of $\text{RSC}_{60}^{\bullet}$ decreased rapidly above room temperature. The reversibility of the alkylthiyl radical addition was attributed to the weaker fullerene-sulfur bond.¹⁵ Strong evidence for this was further provided by observing the change of the light amber color of the solution of phenylthiyl radical adducts ($\text{PhSC}_{60}^{\bullet}$) into the purple color of C_{60} after ceasing irradiation.⁴ This observation indicates that this radical addition, in contrast to the alkoxy fullerenyl derivatives, is reversible.¹¹²

In a few cases, the cleavage of the carbon-sulfur bonds of RSSR was observed, which led exclusively ($\text{R} = \text{benzyl}$) or partially ($\text{R} = t\text{-butyl}$) to the radicals of the type $\text{RC}_{60}^{\bullet}$, particularly if the light was not filtered through the Ni/Co sulfate solution.¹⁵ Molecular mechanics calculations performed for $\text{CH}_3\text{SC}_{60}^{\bullet}$ indicated, in accordance to the corresponding ethyl adduct,¹¹ a preference for an asymmetric conformation for this radical, that is, the methyl group of the CH_3S moiety is placed directly above one of the two 6-membered fused rings of C_{60} (Figure 3).¹⁵

Scheme 19 Addition of alkylthio radicals to C_{60} .

Figure 3 The preferred asymmetric conformation of $\text{CH}_3\text{SC}_{60}^{\bullet}$ radical.

tert-Butylperoxy radicals ($t\text{-BuOO}^\bullet$) add to fullerenes C_{60} and C_{70} in a stepwise radical addition manner to afford a mixture of products with different number of *tert*-butylperoxy groups attached on the fullerene cage.^{113–116} For C_{60} , this reaction gave adducts with the general formula $\text{C}_{60}(\text{O})_m(\text{OO}t\text{Bu})_n$ ($m = 0, n = 2, 4, 6$; $m = 1, n = 0, 2, 4, 6$) through a stepwise cyclopentadienyl addition mechanism.^{113,114} Low concentration of *tert*-butylperoxy radicals, long reaction time, and irradiation of visible light favor epoxide formation [i.e., $\text{C}_{60}(\text{O})(\text{OO}t\text{Bu})_4$], whereas high concentration of *t*-butylperoxy radical favors homo-peroxy adducts [i.e., $\text{C}_{60}(\text{OO}t\text{Bu})_6$].¹¹⁴ On the other hand, no epoxy moiety was present on the corresponding products of C_{70} [$\text{C}_{70}(\text{OO}t\text{Bu})_n, n = 2, 4, 6, 8, 10$], which were formed through both equatorial and cyclopentadienyl addition modes.¹¹⁵ Other peroxy radicals such as cumyl peroxy radical [$\text{Ph}(\text{Me}_2)\text{COO}^\bullet$] react similarly with C_{60} in the presence of a catalytic amount of $\text{Ru}(\text{PPh}_3)_3\text{Cl}_2$, but in this case it was difficult to purify the mixture formed.¹¹⁴

In another study, Troshin *et al.* showed that the reaction of C_{60} with acyl hypohalogenites CF_3COOBr or CF_3COOI —formed *in situ* from CF_3COOAg and Br_2 or I_2 , respectively—in the presence of water results in the formation of an orthoester-type 1,3-dioxolanofullerene in good yield (Scheme 20).¹¹⁷ This method, however, is limited to a specific range of substrates that are stable toward radical halogenation.¹¹⁷

More recently, a facile synthesis of a series of C_{60} -fused 1,3-dioxolanes has been achieved by the $\text{Fe}(\text{ClO}_4)_3$ -promoted reaction of C_{60} with aldehydes or ketones (Scheme 21).¹¹⁸

Scheme 20 Reaction of C_{60} with CF_3COOI .

Scheme 21 Ferric perchlorate-mediated reaction of C_{60} with aldehydes ($\text{R}^1 = \text{H}$) and ketones.

4 PHOSPHORUS-CENTERED RADICALS

So far, only a few phosphorus-centered radicals have been reported to add to C_{60} and C_{70} .^{1, 8–10, 28, 30, 119–122} Owing to the exceptionally high constants of hyperfine coupling of the unpaired electron with the phosphorus nucleus, phosphoryl radicals can be utilized as “paramagnetic reporters”.¹ Phosphoryl radicals have been prepared either by the photolysis of diphosphoryl mercury compounds (Scheme 22)^{1, 10, 28, 30, 119–121} or by hydrogen abstraction from the appropriate hydrophosphoryl compound.^{9, 122}

Similar to the alkylfullerenyl radicals,^{13, 27} the unpaired electron in the phosphoryl-fullerenyl radicals is delocalized mainly over the two six-membered rings adjacent to the C–P bond.^{1, 123} Moreover, a rotation barrier of $4.8 \text{ kcal mol}^{-1}$ was calculated for the radical $^\bullet\text{C}_{60}\text{P}(\text{O})(\text{O}i\text{Pr})_2$.¹²⁴

Scheme 22 Addition of $^\bullet\text{P}(\text{O})(\text{OR})_2$ radicals derived from photolysis of diphosphoryl mercury compounds to C_{60} and C_{70} .

5 SI-CENTERED RADICALS

Hydrogen atom abstraction from silanes (HSiR_3) by photolytically generated *tert*-butoxyl radicals generates trialkylsilyl radicals which add to C_{60} to afford $\text{R}_3\text{SiC}_{60}^\bullet$ radicals.¹⁴ The Si– C_{60} bond is slightly longer than the C– C_{60} bond in an alkyl fullerenyl radical, thus exhibiting a lower rotational barrier compared to their alkyl analogs.

Silylated fullerenes have been prepared by the addition of silyl radicals generated upon photolysis of the corresponding di- or polysilane.^{125–130} For example, the 1,16-bissilylated adduct was isolated as the major product upon reaction of C_{60} with trialkylsilyl radicals $\text{R}_3\text{Si}^\bullet$ (Scheme 23).^{125–127} On the other hand, aryl-substituted silyl radicals generated upon photolysis of the corresponding unsymmetrical disilanes add to C_{60} to afford, apart from the 1,16-bisadduct, an unexpected 1,2-adduct in which the silyl and phenyl groups are attached on the 1,2-positions of C_{60} (Scheme 23).^{125,126} In

some cases, this latter adduct was the only isolated product.¹²⁶

Disilylcyclobutanes (Scheme 24)^{131,132} and cyclotetrasilanes (Scheme 25)^{131,133} also react with C_{60} through the formation of an intermediate Si-centered biradical generated upon photolytically induced cleavage of the four-membered ring, followed by a formal cycloaddition to the [6,6] double bond of C_{60} .

6 METAL-CENTERED RADICALS

Rhenium pentacarbonyl radicals $^\bullet\text{Re}(\text{CO})_5$ —generated upon photodissociation of the Re–Re σ -bond in $\text{Re}_2(\text{CO})_{10}$ —add to C_{60} in benzene to form $\text{C}_{60}[\text{Re}(\text{CO})_5]_2$.¹³⁴ This adduct was similarly obtained from the thermal reaction of C_{60} with $(\eta^3\text{-Ph}_3\text{C})\text{Re}(\text{CO})_4$ —a known source of $^\bullet\text{Re}(\text{CO})_5$ —in the presence of CO (Scheme 26). The compound $\text{C}_{60}[\text{Re}(\text{CO})_5]_2$ is unstable and decomposes at room temperature.¹³⁴

Scheme 25 Photochemical addition of cyclo-(Ar₂Si)₄ to C₆₀.

Scheme 26 Addition of pentacarbonylrhenium radicals to C₆₀.

Tumanskii *et al.* have shown that photolysis of *cis*-(CF₃)₂CF–Hg–Pt(PPh₃)₂–CH=CPh₂ generates the platinum-centered free radical [•]Pt(PPh₃)₂–CH=CPh₂, which add to C₆₀ to afford a moderately stable platinum containing fullerenyl radical *cis*-Ph₂C=CH–Pt(PPh₃)₂–C₆₀.¹³⁵ EPR studies revealed, in addition to this radical adduct, the presence of products of multiple addition of carbon-centered fluorinated radicals formed upon homolysis of the (CF₃)₂CF–Hg bond.¹³⁵

Moreover, Hirsch *et al.* have shown that thermal treatment of benzene solutions of C₆₀ with a 20-fold excess of Bu₃SnH leads to a regioselective 1,2-hydrostannylation of [60]fullerene (Scheme 27).¹³⁶

7 ADDITION OF HYDROGEN ATOM(S)

Hydrogenated C₆₀ radicals (HC₆₀[•]) have been generated by (i) photolysis of di-*t*-butylperoxide to produce *t*-butoxy radicals, which in turn abstract a hydrogen atom from an alcohol, (ii) photoreduction of acetophenone, benzophenone, or acetone in the presence of various alcohols (i.e., 2-propanol), (iii) photolysis of thiophenol, tri-*n*-butyltin hydride, or 1,4-cyclohexadiene in a C₆₀-saturated benzene solution, (iv) by reacting C₆₀ with hydrogen atoms followed by matrix isolation in cyclohexane at 77 K¹³⁷ or neon at 4 K,¹² and (v) in the presence of atomic hydrogen from a microwave discharge.^{12,137,138} In the first two methods, in

Scheme 27 Addition of tributyltin hydride to C₆₀ in refluxing benzene.

which a hydrogen atom abstraction from alcohols by *tert*-butoxy radical or by photoexcited carbonyl group of various ketones occurs, the formation of $\text{HC}_{60}^{\bullet}$ is the result of a sequential electron/proton transfer reaction:

where $\text{R}^1\text{R}^2\dot{\text{C}}(\text{OH})$ derives from activated alcohol or photoreduced ketone in the first and second method, respectively. The generation of $\text{HC}_{60}^{\bullet}$ has been also studied by means of electrochemistry (i.e., protonation of the radical anion of C_{60}).^{139,140} As with alkyl fullereryl radicals ($\text{RC}_{60}^{\bullet}$),^{7,8,32,33,141} $\text{HC}_{60}^{\bullet}$ tend to dimerize to $(\text{C}_{60}\text{H})_2$.^{137,142}

Hydrogen atoms have been used also for the hydrogenation of fullerite (a mixture of crude C_{60} and C_{70}) at elevated temperatures (400°C) under high hydrogen pressure in the presence of iodoethane.¹⁴³ Analysis of the reduced fullerite by fast atom bombardment mass spectrometry (FAB MS) revealed a mixture of hydrofullerenes comprising mainly $\text{C}_{60}\text{H}_{36}$ and $\text{C}_{70}\text{H}_{36}$.¹⁴³

The addition of hydrogen atoms to C_{70} has been achieved by irradiation of C_{70} in dry benzene solution containing benzophenone and isopropanol. This reaction afforded adducts of five different types: four isomers of HC_{70} and a single isomer of H_3C_{70} .¹⁴⁴ At the same time, three of the five possible isomers of $\text{HC}_{70}^{\bullet}$ were detected by ESR studies upon photolysis of a saturated benzene solution containing 1,2-cyclohexadiene.³⁸

8 ADDITION OF HALOGENS

Halogenation of fullerenes is a radical process and can be achieved for fluorination, chlorination, and bromination, but not iodination.^{145–150}

Fluorination of C_{60} has been achieved through the reaction of C_{60} with fluorine gas (F_2), metal fluorides (e.g., MnF_3 , K_2PtF_6 , CoF_3 , TbF_4 , CeF_4), or noble gas fluorides (e.g., XeF_2 , KrF_2), or less efficiently with halogen fluorides (e.g., BrF_5 , IF_5).¹⁴⁹ Except $\text{C}_{60}\text{F}_{48}$,^{151–154} direct fluorination of C_{60} with F_2 results in a mixture of C_{60}F_n with a wide range of compositions.^{145,146} A more selective fluorination method of C_{60} is the high-temperature treatment of metal fluorides (MnF_3 , CoF_3 , K_2PtF_6 ,

etc.) in the presence of C_{60} . For example, MnF_3 leads selectively to the formation of $\text{C}_{60}\text{F}_{36}$,¹⁵⁵ whereas fluorination of C_{60} with K_2PtF_6 affords $\text{C}_{60}\text{F}_{18}$.¹⁵⁶ Several other examples can be found in the literature.^{145,146,157,158} Fluorination of lower polyfluorofullerenes by fluorine also proceeds by a radical mechanism.¹⁵⁰ As for C_{70} , Morton *et al.* reported the detection by EPR spectroscopy of four isomers of FC_{70} derived from the addition of fluorine atoms (from SF_5Cl) to C_{70} .¹⁵⁹ Moreover, it has been shown that fluorination of C_{70} by MnF_3 affords a mixture of $\text{C}_{70}\text{F}_{36/38/40}$ with $\text{C}_{70}\text{F}_{38}$ as the major product.¹⁵⁵

Apart from polyfluoro[60]fullerenes, polychloro derivatives of C_{60} have been also studied.^{145,146,160} Chlorination of C_{60} by chlorine gas at 250°C gives a light orange mixture of chlorinated fullerenes C_{60}Cl_n where an average of 24 chlorine atoms have been attached to C_{60} .¹⁶¹ Reaction of C_{60} with an excess of iodine monochloride (ICl), in either benzene or toluene, produces mainly C_{60}Cl_6 , which was proved to be isostructural with C_{60}Br_6 .^{162,163} The synthesis of C_{60}Cl_6 in toluene is slower than in benzene, indicating that a radical mechanism is operative since toluene is a good radical scavenger. More recently, the preparation of other highly chlorinated [60]fullerenes, including $\text{C}_{60}\text{Cl}_{24}$,¹⁶⁴ $\text{C}_{60}\text{Cl}_{28}$,¹⁶⁵ and $\text{C}_{60}\text{Cl}_{30}$,^{165,166} has been reported.¹⁶⁷ The aforementioned synthesis have been achieved by treating C_{60} with chlorinated agents such as VCl_4 , ICl , ICl_3 , or SbCl_5 .^{165,166,168} Chlorination of C_{70} with ICl in benzene leads to the C_s symmetric compound $\text{C}_{70}\text{Cl}_{10}$.¹⁶⁹ More recently, the preparation of highly chlorinated derivatives of C_{70} , such as $\text{C}_{70}\text{Cl}_{28}$ ¹⁷⁰ and $\text{C}_{70}\text{Cl}_{16}$,¹⁷¹ as well as of higher fullerenes such as $\text{C}_{80}\text{Cl}_{12}$,¹⁷² $\text{C}_{84}\text{Cl}_{32}$,¹⁷³ $\text{C}_{76}\text{Cl}_{18}$,¹⁷⁴ $\text{C}_{76}\text{Cl}_{24}$,¹⁷⁵ $\text{C}_{76}\text{Cl}_{34}$,¹⁷⁶ has been reported.

Bromination of fullerenes is also a radical process. Treatment of C_{60} with neat bromine affords the bromofullerene $\text{C}_{60}\text{Br}_{24}$, which is a yellow orange crystalline compound.¹⁷⁷ This reaction proceeds in a stepwise manner to give successively C_{60}Br_8 , $\text{C}_{60}\text{Br}_{14}$, and finally $\text{C}_{60}\text{Br}_{24}$.¹⁷⁸ On the other hand, bromination of C_{60} with bromine in benzene or CCl_4 affords C_{60}Br_6 , whereas in CS_2 or CHCl_3 affords C_{60}Br_8 .¹⁷⁹ It was later found that C_{60} reacts with bromine in organic solvents (i.e., 1,2- and 1,3-dichlorobenzene, 1,2-dibromobenzene, 1,2,4-trichlorobenzene, chlorobenzene, bromobenzene, and CS_2) to afford bromides C_{60}Br_6 ,

$C_{60}Br_8$, or $C_{60}Br_{24}$ depending on the bromine concentration.¹⁸⁰ Similarly, the bromination of C_{70} in neat bromine, in *o*-dichlorobenzene, or in carbon disulfide produces $C_{70}Br_{10}$.¹⁸¹

9 ION RADICAL REACTIONS OF FULLERENES

Apart from the radical reactions involving neutral radical species, fullerene radical chemistry involves radical ion reactions, that is, the reactions of the radical anion ($C_{60}^{\bullet-}$) or radical cation ($C_{60}^{\bullet+}$) of C_{60} generated upon photoinduced or in some cases thermally induced electron transfer processes.^{1,182} In this section, we will describe some of the most outstanding and representative examples of this type.

9.1 Addition of Amines to C_{60}

Typically, the addition of primary and secondary aliphatic amines to C_{60} is initiated by a

single-electron transfer (SET) process (from amine to C_{60}) to afford a radical ion pair, namely C_{60} radical anion ($C_{60}^{\bullet-}$) and amine radical cation ($R_2NH^{\bullet+}$).¹⁸³ This process is favored in polar solvents.

As an example, the reaction between an excess of a secondary amine, namely morpholine, and [60]fullerene in the presence of oxygen affords exclusively dehydrogenated aminoadducts with a defined 1,4-addition pattern of the amino groups (i.e., bismorpholino[60]fullerene, tetrakis(morpholino)[60]fullerene epoxide) as well as morpholino[60]fullerene dimer (Scheme 28).¹⁴¹ The presence of a free-radical mechanism is strongly supported by this addition pattern as first reported for free-radical additions to [60]fullerene by Krusic *et al.* (i.e., successive 1,4-radical additions to the [5]radialene structure of [60]fullerene to generate a pentaalkylated C_{60} , see Scheme 1).⁵ The reaction of [60]fullerene with piperidine showed similar results.¹⁴¹

More recent advances included the one-step multiple addition of amines to C_{60} , under either photochemical or thermal aerobic conditions, for the synthesis of tetra(amino)fullerene epoxides in moderate to excellent yields (Scheme 29).^{184,185}

Scheme 28 Reaction of morpholine with a benzene solution of C_{60} in the presence of oxygen.

Scheme 29 Oxygenative tetraamination of C_{60} .

Under the photochemical conditions, the tetrakis-morpholino [60]fullerene epoxide has been prepared in a much higher yield compared to that described above for the thermal conditions.¹⁸⁴ After careful reexamination of this photoreaction, it was found that addition of dimethylsulfoxide (DMSO) to the reaction mixture allows the reaction to take place without photoirradiation.¹⁸⁵ This latter tetraamination reaction of [60]fullerene with secondary aliphatic amines was found to be far superior to the photochemical method in terms of the range of applications and the product yield.¹⁸⁵

The radical photoaddition of mono *N*-substituted piperazines to C₆₀ was later reported by Troshin *et al.*¹⁸⁶ The reactions of C₆₀ with piperazines bearing bulky electron-withdrawing groups (i.e., 2-pyridyl, 2-pyrimidinyl) were found to be the most selective and yielded C₆₀(amine)₄O as major products accompanied with small amounts of C₆₀(amine)₂. On the other hand, interactions of fullerene with *N*-methylpiperazine and *N*-(*tert*-butoxycarbonyl) piperazine were found to have low selectivity due to different side reactions.¹⁸⁶

Glycine esters (H₂NCH₂COOR) add directly to C₆₀ upon photolysis to form pyrrolidine ring-fused fullerenes (Scheme 30).¹⁸⁷ The photochemical reactions between C₆₀ and sarcosine esters (CH₃NHCH₂COOR), which have one more methyl group than their glycine analogs, yielded the same pyrrolidine derivatives C₆₀(ROOCCNHCHCOOR) along with another pyrrolidine-type derivative C₆₀-(CH₂N(Me)CHCOOR).¹⁸⁷ The initial addition of a ¹O₂-mediated C-centered radical to C₆₀ and a C–N bond breakage are among the most critical steps involved in the reaction mechanism (Scheme 30).¹⁸⁷ It was later found that the reaction between

glycine- or sarcosine-methyl ester and C₆₀ can be effectively controlled by different iodo-reagents, namely DIB [(diacetoxyiodo)benzene], DIB-I₂, or I₂.¹⁸⁸

The addition of tertiary amines to C₆₀ is also a radical process.^{189–193} The reaction in this case takes place at the carbon α to the nitrogen of the amine. The intervention of singlet oxygen (¹O₂) in the radical reaction of C₆₀ with tertiary amines (i.e., triethylamine) has been proposed when the reaction is carried out in the presence of molecular oxygen or in air-saturated solutions.^{189,190} A plausible reaction mechanism involves primary interaction of singlet oxygen with the amine followed by addition of the resulting radical to the fullerene to afford, after repeating the same sequence of proton and electron transfer steps, the final pyrrolidine adduct of C₆₀ (Scheme 31).^{189,190}

On the other hand, when the photochemical addition of triethylamine to C₆₀ is carried out in deoxygenated toluene, the major product obtained is the corresponding adduct RC₆₀H (Scheme 32).¹⁹⁰ Similar to that of primary and secondary amines, the mechanism proposed for the photoreactions between [60]fullerene and tertiary amines (i.e., Et₃N) starts with a photoinduced electron transfer (PET) from the amine to photoexcited [60]fullerene, to give a radical ion pair.^{190–193} This is followed by deprotonation of the amine cation radical (R₃N^{•+}) by [60]fullerene anion radical (C₆₀^{•−}) to yield the corresponding radical pair, which combine to afford the final adducts (Scheme 32). The final monoadduct can react further through similar electron/proton transfer and radical pair recombination processes to afford the corresponding cycloadducts.^{191,192}

Similar to the reaction of C₆₀ with glycine- or sarcosine- methyl ester (Scheme 30),^{187,188} pyrrolidine ring-fused fullerene multicarboxylates have been produced upon photolysis of aminopolycarboxylic esters in the presence of C₆₀.¹⁹⁴ For example, irradiation of the tetramethyl ester of ethylenediaminetetraacetic acid (EDTA) with C₆₀ afforded the corresponding EDTA-containing fullerene monoadducts along with two adducts where the nitrogen ethylene bond N–CH₂CH₂ of EDTA has been broken (Scheme 33). Similar results were observed with pentamethyldimethylethylenetriaminepentaacetate (DTPA).¹⁹⁴ Aminocarboxylic acids are also reactive toward C₆₀ under photochemical conditions, affording upon decarboxylation

Scheme 30 Photochemical reaction of C₆₀ with glycine and sarcosine esters.

Scheme 31 Proposed mechanism for photocycloaddition of tertiary amines to C_{60} .

Scheme 32 Proposed mechanism of photoreaction between [60]fullerene and triethylamine.

Scheme 33 Photochemical reaction of C_{60} with tetramethyl ethylenediaminetetraacetate.

the corresponding organodihydrofullerenes.¹⁹⁴ A radical mechanism has been proposed for these photochemical reactions.¹⁹⁴ A series of similar pyrrolidinofullerenes bearing ester group

functionalities has been prepared through the $\text{Pb}(\text{OAc})_4$ -mediated reaction of [60]fullerene with the methyl esters of nitrilotriacetic acid, EDTA, and hexamethylenediaminetetraacetic acids.¹⁹⁵

Scheme 34 Reactions of C₆₀ with Et₃N in the presence or absence of aldehydes.

In 2006, Wang *et al.* reported that thermal reactions of [60]fullerene with amino acid ester hydrochlorides and triethylamine in refluxing *o*-dichlorobenzene afford pyrrolidinofullerene derivatives containing a CH₃CH fragment derived from Et₃N through C–N bond cleavage.¹⁹⁶ Further investigations revealed interesting reactions between C₆₀ and tertiary amines or reactions of C₆₀ with tertiary amines and aldehydes, which afford cyclopentafullerene derivatives with high stereoselectivity (Scheme 34).¹⁹⁶ These reactions are initiated by an electron transfer from amine to C₆₀ to form the corresponding amine radical cation and C₆₀^{•−}, respectively.

Scheme 35 Formation of organofullerenes RC₆₀R' through the reaction of C₆₀^{2−} with alkyl halides.

upon radical coupling with C₆₀^{•−}, the intermediate RC₆₀[−] (Scheme 35). The final alkylation of RC₆₀[−] with RX or R'X takes place via an S_N2 mechanism (Scheme 35).

9.2 Addition of Alkyl Halides to C₆₀

The formation of organo[60]fullerenes of the type R₂C₆₀ or RR'C₆₀ has been described to occur via combination of electron transfer and S_N2 reactions from C₆₀^{2−} and alkyl halides (RX or R'X) in benzonitrile (Scheme 35).¹⁹⁷ It has been proposed that the first step of this reaction involves an electron transfer from C₆₀^{2−} to RX to form an intermediate radical pair C₆₀^{•−} and R'X^{•−}. The R–X bond is cleaved upon dissociative electron transfer to afford,

9.3 Addition of Ketene Silyl Acetals and Allylic Stannanes to C₆₀

The first step in the monoaddition reaction of ketene silyl acetals to fullerene includes a photoinduced SET from ketene silyl acetals to the triplet excited state of C₆₀ (Scheme 36).^{198,199} Radical coupling leads to a zwitterionic species, which upon water-assisted removal of the silyl group and protonation, affords the final adducts. No free-radical species are involved since the addition of a radical trap (i.e., TEMPO) had no effect on the reaction.

The mono- and penta-addition of enol silyl ethers to C₆₀ was later reported.²⁰⁰ In particular, it was

Scheme 36 Photoinduced C–C bond formation of C₆₀ with ketene silyl acetals.

found that the reaction of 1-alkoxy-1-siloxyethene with C_{60} in 20% DMSO/chlorobenzene at ambient temperature under O_2 atmosphere affords a penta-addition product, while the reaction of 1-alkoxy-1-siloxyalkenes or 1,2-siloxyalkenes under argon atmosphere affords monoaddition products.²⁰⁰

Apart from ketene silyl acetals, allylic stannanes can also efficiently add to C_{60} via photoinduced electron transfer to the triplet excited state of C_{60} .^{201,202}

9.4 One- and Two-Electron Reduction of C_{60} with NADH and NAD Dimer Analogs

The triplet excited state of C_{60} has a reduction potential of $E_{red}^0 = 1.14$ V versus standard calomel electrode (SCE) and thus a variety of organic compounds can reduce C_{60} to the C_{60} radical anion. In homogeneous systems, however, fast back-electron transfer to the reactant pair results generally in an extremely short lifetime of the generated $C_{60}^{\bullet-}$ and no net formation of $C_{60}^{\bullet-}$ is observed. To overcome these problems, Fukuzumi *et al.* used nicotinamide adenine dinucleotide (NADH) analogs as electron donors.²⁰³ In particular, it was found that the photoinduced electron transfer from an NADH analog 1-benzyl-1,4-dihydronicotinamide (BNAH) and the dimer analog [(BNA)₂] to the triplet excited state of C_{60} ($^3C_{60}^*$) yields stable $C_{60}^{\bullet-}$ in benzonitrile solution with a high quantum yield.²⁰³ The reaction mechanism in the latter process is initiated by an electron transfer from (BNA)₂ to the triplet excited state ($^3C_{60}^*$) followed by fast C–C bond cleavage

Scheme 37 Selective one-electron reduction of C_{60} via photoinduced electron transfer from 1-benzyl-1,4-dihydronicotinamide dimer (BNA)₂ to $^3C_{60}^*$.

in the resulting $(BNA)_2^{\bullet+}$ to give $BNA^{\bullet}$ and BNA^+ . A second electron transfer from $BNA^{\bullet}$ to C_{60} yields BNA^+ and $C_{60}^{\bullet-}$ (Scheme 37).²⁰³

When BNAH is replaced by 4-*tert*-butylated BNAH (*t*-BuBNAH), the photochemical reaction with C_{60} yields selectively instead of the $C_{60}^{\bullet-}$ the *tert*-butylated anion (*t*-Bu $C_{60}^{\bullet-}$).²⁰³ The selective two-electron reduction of C_{60} to 1,2-dihydro[60]fullerene (1,2- $C_{60}H_2$) was also achieved by using another NADH analog 10-methyl-9,10-dihydroacridine (AcrH₂) under visible light irradiation in deaerated benzonitrile solution containing trifluoroacetic acid (Scheme 38).²⁰³ This reaction proceeds via photoinduced electron transfer from AcrH₂ to $^3C_{60}^*$, followed by proton transfer from AcrH₂^{•+} to $C_{60}^{\bullet-}$ and a second electron transfer from the deprotonated acridinyl radical (AcrH[•]) to $HC_{60}^{\bullet-}$ in the presence of trifluoroacetic acid, to yield the final products 10-methylacridinium ion (AcrH⁺) and 1,2- $C_{60}H_2$ (Scheme 38).

Scheme 38 Selective two-electron reduction of C_{60} to $C_{60}H_2$ via photoinduced electron transfer.

9.5 Cation Radical Reactions of C₆₀

Initially, Foote *et al.* reported the generation of the radical cation of C₆₀ via electron transfer to singlet *N*-methylacridinium hexafluorophosphate (NMA⁺).²⁰⁴ Higher yield production of C₆₀^{•+} could be achieved by cosensitization, using high concentrations of biphenyl to form biphenyl radical cation which is the ultimate oxidant for C₆₀.²⁰⁴ Later, Schuster *et al.* reported the generation of C₆₀ radical cations by photosensitized electron transfer from electronically excited 1,4-dicyanoanthracene (DCA), which resulted in the addition of alcohols or hydrocarbons to C₆₀.²⁰⁵ Mattay *et al.* also reported the generation of C₆₀^{•+} via photoinduced electron transfer.^{206,207} It was later found that, when 2,4,6-triphenylpyrylium tetrafluoroborate (TPP⁺BF₄[−]) is used as a sensitizer, an electron transfer from C₆₀ to TPP occurs without the application of a cosensitizer.²⁰⁸ The existence of C₆₀^{•+} has been proved by using ESR studies.²⁰⁸ The proposed mechanism for the formation of C₆₀^{•+} by the aforementioned cosensitization method is depicted in Scheme 39.

The generated radical cation C₆₀^{•+} abstracts a hydrogen atom from the appropriate H-donor (i.e., *tert*-butylmethyl ether, propionaldehyde, *N,N*-dimethylformamide, 1,3-dioxolane, phenylacetaldehyde, methyl formate, *tert*-butanol, propionic acid, glycol and methoxyethanol) to give, after reduction of HC₆₀⁺ to HC₆₀[•] (i.e., from reduced sensitizer) and recombination with R[•], the corresponding 1-substituted 1,2-dihydro[60]fullerenes (Scheme 40).^{206,207}

10 CONCLUSIONS

In this article, we have outlined some of the progress made in the radical chemistry of fullerenes from both practical and fundamental points of view.

From a fundamental perspective, we have shown that ESR spectroscopic studies have provided valuable insight into the basic characteristics of the radical reactions of fullerenes. These and other physical/chemical studies have led to the establishment of key features of the radical reactions of fullerenes, some of which are as follows: (i) the rate constants for the addition of various C-centered radicals to fullerene are two orders of magnitude higher than those for the addition of radicals to a wide class of monosubstituted unsaturated compounds; (ii) the multiple addition of free radicals to C₆₀ results in stable fullereryl radicals with an allylic or cyclopentadienyl structural pattern; (iii) the unpaired electron in the RC₆₀[•] radical adducts is essentially confined to definite carbon atoms incorporated into the two hexagons adjacent to the radical center and is not extensively delocalized over the C₆₀ sphere; (iv) fullereryl radicals demonstrate a tendency to dimerize in a “head-to-head” type; (v) there is a hindered rotation about the R–C₆₀[•] bond in the alkyl fullereryl radicals, whereas the rotation barrier is lower for the Si–C₆₀[•] radicals owing to the slightly longer bond of Si–C₆₀ compared to C–C₆₀.

From a practical point of view, the employment of radical reactions in fullerene chemistry has led to the synthesis of a variety of structurally diverse fullerene derivatives which would be otherwise inaccessible. Such reactions include the addition of

Scheme 40 Reaction of C₆₀^{•+} with organic hydrogen donors RH.

radicals of different chemical nature, including C-, Si-, O-, S-, P-, and metal-centered radicals, to C₆₀ and/or C₇₀.

Some of the most recent developments outlined in this article, as well as the ongoing research interest on the radical reactions of fullerenes, convey that there are more, still unexplored radical reactions that will likely emerge in the future.

Tin Hydrides and Functional Group Transformations

Hannelore Jasch and Markus R. Heinrich

*Department für Chemie und Pharmazie, Friedrich-Alexander-Universität Erlangen-Nürnberg,
Pharmazeutische Chemie, Erlangen, Germany*

1 INTRODUCTION

There is probably hardly any reagent that organic chemists would associate more with radical chemistry than tributyltin hydride. Unfortunately, this popularity is also the reason for a certain reluctance among chemists to apply radical reactions since the toxicity and the sometimes troublesome removal or purification are known as well as the reagent itself. In this article, we give an overview of the manifold reaction types that have so far been put into practice by employing tin hydrides. Since several new tin reagents have been reported in recent years together with improved reaction conditions, significant advances could be made over the above-mentioned disadvantages associated with the traditional organostannanes. In this way, the whole field of tin hydride-mediated radical reactions becomes increasingly attractive, as a variety of modern replacements are now available for the still widely used tributyltin hydride.

As it often happens in chemistry, major advances arise from observations that are first regarded as experimental failures. When van der Kerk and his group attempted the hydrostannylation of allyl bromide (**1**) with triphenyltin hydride (**2**) by performing a reaction type that was already well established at that time, they were surprised to find propene (**3**) as a reaction product.¹ Instead of forming the desired adduct **4**, triphenyltin hydride (**2**) had effectively removed the allylic bromine atom

by radical chain mechanism requiring only trace amounts of an initiator which most probably was oxygen (Scheme 1).

The new method for the deoxygenation of secondary alcohols, which was reported by Barton and McCombie in 1975, considerably increased the interest in radical chemistry, and especially in tin hydrides.² Under mild conditions, and avoiding rearrangements caused by alternative cationic intermediates, hydroxy groups could now be selectively removed from structurally complex compounds. An example from the field of sugar chemistry, which has been part of Barton's first article, is depicted in Scheme 2. The secondary alcohol **5** was first converted to xanthate **6** and then reduced in the presence of tributyltin hydride (**7**) to give the corresponding deoxygenated carbohydrate **8**.

The deoxygenation methodology, which was initially limited to secondary alcohols, could later be successfully extended to primary and tertiary alcohols by varying the reaction conditions and structural modifications of the original dithiocarbonate. Even today, and mainly due to the mild reaction conditions, the Barton–Combie deoxygenation is one of the methods of choice in natural product synthesis. In many cases, dispensable oxygen-containing substituents have to be removed in the final stages, which had earlier been required to build up the desired carbon skeleton.³

Scheme 1 Radical dehalogenation of allyl bromide (1) by triphenyltin hydride (2).¹

Scheme 2 Barton–McCombie deoxygenation of the secondary alcohol 5.²

In the 1980s and 1990s, a large number of reports in the field of radical chemistry appeared disclosing many new transformations using tin hydrides as key reagents. At the same time, the attempts to address the disadvantages were also beginning to intensify. Tris(trimethylsilyl)silane (see **Silanes as Reducing Reagents in Radical Chemistry**) was introduced as a potential replacement, and a growing community of investigators started to feel that it was time to start the “flight from the tyranny of tin”.⁴

Owing to the limitations of space, it will be impossible to comprehensively cover the whole field of radical tin hydride chemistry in this article. As the newly developed tin reagents and related reaction conditions can be considered as a key to the future applications of tin hydrides, we will first focus on this issue. In the second part, we will show which functional groups can act as radical sources in tin hydride-mediated reactions. Illustrative examples have been chosen to give insight into the large variety of radical transformations feasible by employing tin hydrides. For further reading, the reader is referred to a number of reviews that have

appeared covering the field of radical tin hydride chemistry.^{5–23} An excellent article has recently been published by Clark.²⁴

2 TIN HYDRIDES

2.1 Preparation of Tin Hydrides

Organostannanes, which represent derivatives of stannane (SnH_4), show an increasing thermal stability when more hydrogen atoms are replaced by alkyl or aryl groups. While stannane itself readily decomposes to tin and hydrogen, trialkyl or triaryl-stannanes can be stored and handled much more conveniently.²⁵ Among the organostannanes that are used in radical chemistry, tributyltin hydride (7) is certainly the most important congener. Similar to its triphenyl derivative 2, it is usually prepared from the corresponding organotin chlorides by reaction with sodium borohydride^{26–29} (Scheme 3) or lithium aluminum hydride.^{30–40}

Scheme 3 Preparation of triphenyl and tributyltin hydride (2 and 7) by reduction of organotin chlorides with sodium borohydride.²⁸

Scheme 4 Preparation of tributyltin hydride from tributyltin oxide 9 and polysiloxane 10.⁴³

Scheme 5 Preparation of tripropyl and tributyltin hydride by thermal decarboxylation of tin formiates.⁴⁵

Diborane⁴¹ and aluminum hydride⁴² were found to be suitable reagents for the preparation of tin hydrides from alkyl stannyl ethers. The most convenient access to tributyltin hydride (7), although it does not represent the frequently used method (Scheme 3), is the reduction of bis(tributylstannyl) ether (9) with polymethylhydrosiloxane (PMHS, 10) (Scheme 4).⁴³ Because of a favorable equilibrium in exchange reactions of hydrogen, the reducing siloxane 10 can be replaced by other more reactive organostannanes such as diaryltin hydrides.⁴⁴

Alternatively, trialkyltin hydrides such as 7 and 11 can be readily prepared by thermal decarboxylation of the corresponding trialkyltin formiates⁴⁵ (Scheme 5) or by decomposition of organostannyl amines.⁴⁶

In addition to the broad use of tin hydrides as reducing agents, the deuterated or tritiated analogs have been successfully employed in the synthesis of isotope-labeled compounds.^{47,48} Concerning the

preparation of these stannane analogs, two main strategies have been followed. Solvolysis of (triorganostannyl) metal compounds such as R₃SnNa 12,^{49,50} R₃SnLi,⁵¹ or R₃SnMgX^{52–55} with deuterium oxide leads to the desired tin deuterides 13 as well as the reduction of organotin chlorides with dialkyl aluminum deuterides 14 (Scheme 6).⁵⁶

The main drawback of the commonly used organotin hydrides is their comparatively high toxicity, which has to be largely attributed to the good permeability and adsorption of these compounds through the skin.⁵⁷ In general, tin hydrides bearing short alkyl chains, such as trimethyltin hydride, are more difficult to handle because of their higher volatility. In addition to the immediate toxicity of the tin hydride reagents, problems are often again encountered during work-up, and special care has to be taken concerning the final waste disposal. For the separation of remaining organostannanes and related by-products arising from the respective reaction mixtures, several “classical” methods have been established. Given that the desired reaction product is sufficiently polar, the tin-containing compounds can largely be removed by extraction with hydrocarbons from solutions in acetonitrile.⁵⁸ Alternatively, the organostannyl derivatives have been converted to insoluble iodides or fluorides by the use of either

Scheme 6 Preparation of triorganotin deuterides 13.^{49–51, 56}

Scheme 7 Carbon–carbon bond formation via *in situ* formation and regeneration of tributyltin hydride (**7**).⁶²

iodine and DBU (1,8-diazabicycloundec-7-ene) or potassium fluoride.⁵⁹

However, the removal of the tin-containing residues from the reaction mixture by these classical methods is in most cases by far not quantitative. For this reason, and especially due to the fact that applicability of toxic, tin-contaminated products would later be severely restricted, a number of strategies have been developed to make tin hydride-mediated reactions more attractive.

2.2 In situ Generation and Catalytic Reactions

One successful approach to facilitate work-up and separation of tin-containing residues is to run the respective reactions catalytically in tin hydride. On the basis of the pioneering work of Hayashi published in 1967,⁴³ who discovered that organostannanes can efficiently be prepared from siloxanes (Scheme 4), the principle of *in situ* generation of tin hydrides was first put into practice by Grady and Kuivila in 1969.³⁴ Sodium borohydride, which was also known to effect the conversion of tributyltin halides to hydrides, was introduced as an alternative reagent for the *in situ* generation and regeneration of tributyltin hydride by Corey.⁶⁰ Given that the functional groups of the substrates showed sufficient stability toward sodium borohydride, the borohydride–organotin chloride couple emerged as a reagent pair of choice for reactions run catalytically

in tin hydride.⁶¹ An example featuring a catalytic tributyltin hydride-mediated carbon–carbon bond formation is depicted in Scheme 7.⁶² Under photochemical initiation, cyclohexyl iodide (**15**) and methyl acrylate (**16**) were cleanly converted to ester **17** in the presence of only 0.2 mol equivalents of tributyltin chloride.

More recent reports describe the use of siloxanes, activated by potassium fluoride, for the *in situ* regeneration of trialkyltin halides.⁶³ Alternatively, catalytic amounts of tributylstannyl phenyl ether can be employed in combination with siloxanes for the same purpose.⁶⁴ In addition to the above-shown carbon–carbon bond-forming reactions, the catalytic tin hydride-mediated reductions have been shown to be highly useful for the mild removal of nitro and azide groups from alkanes.^{65,66} An interesting review including reactions with catalytic amounts of organotin hydride in combination with PMHS has been compiled by Lawrence.⁶⁷

2.3 Supported Tin Hydride Reagents

A relatively new strategy focusing on the facilitated removal of the tin-containing reagents and products is to employ polymer-bound tin hydrides. The preparation of the macromolecular reagents can be realized in two ways: either the functionalization of an existing polymer with organostannane moieties,^{68,69} or by copolymerization of tin

Figure 1 Polymer-supported trialkyltin hydrides **18**^{72,73} and **19**.⁷⁰

hydride-containing monomers (Figure 1).^{68,70,71} The applicability of such reagents was initially demonstrated in simple reductions of organohalides.⁷²

A later report by Neumann showed that the concept of polymer-bound reagents could moreover successfully be combined with the principle of *in situ* regeneration, so that only substoichiometric amounts of the polymer were required for the reduction of alkyl bromides and iodides.⁷³ The dramatic improvement with respect to the amount of tin-containing residues remaining after work-up, which can be achieved by the use of macromolecular tin hydrides, became obvious from a study by Dumartin.⁷⁴ For comparison, the reduction of 1-bromoadamantane (**20**) with the Bu_3SnCl – NaBH_4 couple to give adamantane (**21**) was first combined with the traditional treatment of the product mixture with potassium fluoride (to give insoluble tributyltin fluoride) or with purification by column chromatography (Scheme 8). The adamantane isolated from these experiments still contained remarkable amounts of tin as 15.2 and 9.8×10^4 ppm, respectively (see table in Scheme 8, entry 1). The application of a polymer-bound dibutyltin iodide (0.5 M equiv with respect to **20**) together with sodium borohydride led to a decrease in tin pollution of the product to only 26 ppm (entry 2). By further reducing the amount of polymer-bound tin hydride to 0.05 molar, the adamantane was obtained cleanly, since no more tin could be detected in the product by inductively coupled plasma mass spectrometry (ICP-MS) (entry 3). Moreover, the tin-containing polymer recovered from the reduction could be reused without a significant loss of reactivity.

To produce polymeric materials with a higher tin hydride loading than that of the so-far-known

macromolecular reagents, solid networks have been prepared from Grignard reagents and phenyltin trichloride.⁷⁵ Upon further treatment with bromine and reduction with sodium borohydride, a highly solvent-penetrable but insoluble tin hydride was obtained. The new reagents showed complete regeneration capability in NaBH_4 , and during their reactions no detectable leaching of tin into the solution was observed.

Remarkable advances with respect to permanent porosity, Sn-H site accessibility, solvent tolerance, and applicability in continuous flow systems have also been achieved with elusion-derived foams.⁷⁶ The new polymer-supported tin hydride reagents of this type were prepared by copolymerization of a stannylated styrene derivative, styrene, and *p*-divinylbenzene.

Since the accessibility of the Sn-H groups within polymeric reagents is an important prerequisite to a successful application, a detailed study concerning the effects of the polymer structure on the reactivity has been conducted. Within this report, effects such as coil formation in the polymer or structural changes due to dilution of the reaction mixture are discussed.⁷⁷

Comparable to polymer-bound tin hydrides, a facilitated work-up was also put into practice with organostannanes attached to polyaromatic hydrocarbons such as pyrene. In this case, separation is achieved by adsorption of the reagents and their by-products on activated carbon.⁷⁸ In a recent study, triarylphosphonium-supported tin hydrides were evaluated as reagents for Stille couplings, radical dehalogenations and cyclizations, as well as carbonyl allylations (Scheme 9).⁷⁹ For this particular reagent type, removal of the tin hydride

20 $\xrightarrow[\text{EtOH}]{\text{SnX/NaBH}_4, \text{AIBN}}$ **21**

	SnX/NaBH ₄	Molar ratio of SnX/ 20	Yield (% adamantane (20))	Tin pollution (ppm)

Scheme 9 Triarylphosphonium-supported tin reagents in radical cyclization reactions.⁷⁹

(generated *in situ* from chloride **22**) from the crude reaction mixture is possible by precipitation upon addition of an unpolar solvent such as hexane. In this way, residual tin amounts as low as 5 ppm were found in the products obtained from a series of dehalogenation reactions. Moreover, separation by precipitation led to a recovery of the triarylphosphonium-supported tin reagents in high purity which enabled their successful recycling and reuse without loss of reactivity. An illustrative example from the same study featuring the radical 5-exo-type cyclization of iodide **23** is shown in Scheme 9. The silicon tether was later cleaved from product **24** by tetrabutylammonium fluoride (TBAF) to give alcohol **25**.

Closely related to polymer support, a high degree of tin removal from the desired products can alternatively be attained in reactions in which a polymer-bound substrate is reacted with standard tributyltin hydrides. Relative rates and approximate rate constants for the corresponding inter- and intramolecular hydrogen-transfer reactions are available from the literature.⁸⁰ A collection of illustrative examples of this reaction type can be found in a review by Ganesan.⁸¹

2.4 Fluorous Tin Hydrides

Owing to their unique properties, fluorinated reagents have become increasingly popular for various purposes in the past two decades. A number of review articles summarizing general developments and advances in this field have appeared.^{82–89}

Pioneering work on polyfluorinated organotin hydrides and their use in radical reactions was

reported by Curran in 1996.⁹⁰ Compared to classical tributyltin hydride, fluorinated derivatives such as $(\text{C}_6\text{F}_{13}\text{CH}_2\text{CH}_2)_3\text{SnH}$ are even slightly more reactive (by a factor of 2) concerning the transfer of hydrogen to a primary carbon radical center.⁹¹ Given a comparable reactivity, the main advantage of the polyfluorinated over classical tributyltin hydride reagents arises from the far less complicated reaction work-up. Separation of polyfluorinated reagents is readily achieved by simple biphasic fluorous–organic extraction. An early application of this technique in radical hydroxymethylation reactions is shown in Scheme 10, together with the underlying reaction mechanism.⁹² Catalytic amounts of the fluorous tin hydride **26** were sufficient to achieve a good conversion of 1-bromoadamantane (**20**) to alcohol **27**, since sodium cyanoborohydride could be employed as a regenerating reagent.

The ability of triorganostannyl radicals to efficiently add to carbon–carbon triple bonds (see also Section 3.3.6) can be exploited to achieve the synthesis of lactam **28** from azaenyne **29** in the presence of carbon monoxide (Scheme 11).^{93,94} Polyfluorinated organostannyl radicals (as available from reagent **26**) proved equally effective for this purpose, and since a vinyltin intermediate **30** is formed from the cyclization introducing the CO unit, the reaction is well suited for combination with a subsequent Stille-type cross-coupling.^{95,96} No purification of **30** was necessary prior to the palladium-catalyzed reaction with iodobenzene (**31**), and the fluorous tin reagent was again easily separated from the crude reaction mixture by extraction with perfluorohexane (FC-72).

The results of an extensive study comparing the properties of eight different fluorous tin hydrides

Scheme 10 Radical hydroxymethylation employing fluorous tin hydrides.⁹²

Scheme 11 Fluorous tin hydride-mediated synthesis of β -lactam **30** combined with a Stille-type cross-coupling reaction.^{95,96}

from three structural subgroups **32**, **33**, and **34** (group 32 includes reagent **26**) have been reported by Curran (Figure 2).⁹⁷ Insights are given on how the substitution pattern and the degree of fluorination influence the respective partition coefficients between perfluorohexanes and common organic solvents, which are important for the easy and quantitative separation during work-up. The reagents were found generally useful for a replacement of tributyltin hydride in stoichiometric as well as in catalytic radical reactions, which gives them an excellent potential for applications in large-scale processes as well as combinatorial and parallel synthesis.

Despite the rapid development of new methodologies employing polyfluorinated reagents,

investigations on improved solvents were largely neglected with the exception of benzonotrifluoride (BTF).⁹⁸ For the reason of solubility, those reactions are ideally conducted in fluorous/organic amphiphilic solvents which readily dissolve both organic and fluorous compounds and lead to a homogeneous reaction medium. Advances in this field were made by the introduction of the perfluorinated ether F-626.^{99,100} An example from the first report on the use of F-626 (**35**) in the reduction of haloalkanes, such as **36**, is depicted in Scheme 12.¹⁰¹ Advantageously, the new fluorinated solvent **35** was easily recovered together with the fluorous tin reagent **26** during work-up by simple extraction with perfluorohexane (FC-72). Moreover, both **26** and **35** could successfully be reused for

**Figure 2** Fluorous tin hydrides.⁹⁷**Scheme 12** Fluorous tin hydride reduction of 1-iodoadamantane (**36**) using the perfluorinated ether F-626 (**35**) as solvent.¹⁰¹

the same reaction type without further purification, which is mainly due to the low partition coefficients observed for general organic solvents to a fluorous phase. In this respect, F-626 proved superior to BTF because of its increased fluorophilicity.

Regarding the separation and recovery of fluorous tin species from crude reaction mixtures, silica tethered with fluorinated chains has been evaluated with respect to its ability to release and capture fluorous tin reagents depending on temperature.¹⁰²

Similar to the reversed strategy presented in Section 2.3, in which polymer-bound substrates were employed instead of supported tin hydride reagents, the difficulty of organotin removal can

alternatively be circumvented by attaching the fluorous side chain to the substrate instead of to the tin reagent. A recent example from a report in which this principle has been put into practice is depicted in Scheme 13.¹⁰³ The radical conjugate addition to substrate **37**, bearing a typical norephedrine-based chiral auxiliary (see **Stereoselective Radical Reactions**) leads to the product **38** which was found difficult to be purified from tin-containing residues. After the same radical reaction was performed with the polyfluorinated derivative **39**, the respective product **40** could easily be separated from remaining tributyltin hydride and its by-products by fluorous solid-phase extraction (FSPE).

**Scheme 13** Comparative study on classical and fluorous chiral auxiliaries in tin hydride-mediated alkylations.¹⁰³

Scheme 14 Water-soluble tin reagents **41** and **44**.^{104,106}

An excellent summary on the developments in the field of fluorinated tin hydrides, including fluororous organotin reagents for allylation reactions, was published by Ryu *et al.*⁹⁶

2.5 Water-Soluble Tin Hydrides

The first water-soluble organotin hydride **41**, in which the three butyl groups of Bu₃SnH were replaced by methoxyethoxypropyl units, was reported by Breslow (Scheme 14).¹⁰⁴ This reagent was successfully used for the reduction of halogenated carbohydrate derivatives and aromatic carboxylates, such as 3-bromobenzoic acid **42**, to give benzoic acid **43** in buffered aqueous solutions. It could easily be recovered in the form of its

chloride during work-up by simple extraction upon acidification with hydrochloric acid. Shortly after, Maitra demonstrated that unmodified tributyltin hydride is also effective as a radical reducing agent in water at elevated temperatures using longer reaction times.¹⁰⁵ To achieve the conversion of certain very unpolar substrates in water, suitable detergents had to be added. Although widely applicable, the main drawback of the etheral tin hydride **41** remained its multistep synthesis from monomethyl glycol. For this reason, the dipotassium salt **44**, which is conveniently prepared from tin metal and acrylic acid, was evaluated with respect to its applicability as a substitute (Scheme 14).¹⁰⁶ An example from the study by Collum is depicted below. *In situ* reduction of the organotin diol **44** by sodium borohydride, and using 4,4'-azobis(4-cyanovaleic acid) (ACVA) (**45**) as initiator, led to the desired

Tin hydride **48** as an ionic reductant

Tin hydride **48** as a radical reductant

Scheme 15 Tin hydride **48** acting as ionic hydride or radical hydrogen donor.¹⁰⁷

cyclization of **46** to dihydrobenzofuran **47** in 1.5% potassium hydroxide solution. Interestingly, **47** was also obtained from **46** in the absence of diol **44** by applying an eightfold excess of sodium borohydride.

Depending on the reaction conditions, the organostannylated *N,N*-dimethylbenzylamine **48** can act as a potent ionic hydride transfer reagent as well as a radical reductant.¹⁰⁷ When applied in protic solvents such as methanol, tin hydride **48** led to the reduction of various ketones to alcohols. As shown in Scheme 15, cyclopropyl methyl ketone (**49**) was cleanly converted to the corresponding alcohol **50**. Interestingly, **49** was not reduced to **50** when the same reaction was attempted in aprotic solvents such as tetrahydrofuran or acetonitrile. Under the latter conditions, **48** behaved like a standard tin hydride-type radical reagent which is able to induce reactions such as the dehalogenation of cyclopropylmethyl bromide **51** to give butene **52** via a fast ring-opening of the radical **53**. Single-electron transfer can be ruled out for the formation of alcohol **50** from **49**, since a radical reaction mechanism of this type would cause ring-opening of the cyclopropane **54** to give 2-pentanone (**55**).

Beneficially, the tin hydride **48** and its by-products could efficiently be removed from crude reaction mixtures by filtration through silica gel, taking advantage of the basic benzylamine moiety. A facilitated work-up and organotin removal was recently also achieved with organotin hydride **56** (Scheme 16).¹⁰⁸ Several test reactions including

reductions of chlorides, bromides, iodides, and selenides as well as Barton–McCombie type deoxygenations, revealed a reactivity of **56** comparable to those of tributyltin hydride (**7**) or triphenyltin hydride (**2**). Within this survey, indanol **57** could be prepared from aryl bromide **58**. As a part of the work-up procedure, the dioxolone moiety of tin bromide **59** was hydrolyzed under mild alkaline (or alternatively acidic) conditions to give the corresponding α -hydroxycarboxylic acid **60**, which was easily separated by alkaline extraction.

2.6 Tin Hydrides for Stereoselective Reactions

Although the main strategies to achieve stereocontrol in radical reactions are based on chiral information from the substrates,¹⁰⁹ there have also been a few attempts to reach this goal by employing chiral reagents. As far as tin hydride chemistry is concerned, the preparation and use of chiral organostannanes was first reported by Curran¹¹⁰ and Metzger.¹¹¹ Concerning their chemical structures, these early reagents were characterized by a divalent binaphthyl backbone and a more or less demanding third alkyl substituent on the tin atom. Shortly after, a chiral tin hydride with a benzylamine substructure was introduced, which is closely comparable to the reagent shown in Scheme 15.¹¹² In a third group of tin hydrides discovered by Schiesser, chirality was created by attaching up to three menthyl groups to the tin center.^{113,114} With these reagents, only moderate yields and enantiomeric excess values

Scheme 16 Radical cyclization mediated by tin hydride **56**.¹⁰⁸

were however at first obtained from reduction of model substrates including α -halogenated esters or ketones. While the performance of the chiral organostannanes of the binaphthyl type could later be improved by a careful optimization of the reaction conditions,¹¹⁵ a major advance was made by combining the menthyl-derived reagents with Lewis acids.¹¹⁶ An example featuring the synthesis of (*S*)-naproxene (**61**) by reduction of bromide **62** with the chiral tin hydride **63** in the presence of magnesium bromide is depicted in Scheme 17. The first application of Lewis acids as additives in tin hydride-mediated radical reactions had earlier been described by Hoshino.¹¹⁷

Moreover, chiral oxazoline-based dialkyltin hydrides have been briefly studied in free-radical addition and cyclization reactions.¹¹⁸ A review

article on asymmetric free-radical reductions mediated by chiral stannanes, germanes, and silanes has recently been prepared by Schiesser.¹¹⁹ Comparable to the chiral tin hydrides mentioned above, which preferentially deliver the hydrogen atom to one or the other enantiotopic side of a planar trivalent carbon-centered radical, sterically more demanding tin hydrides can be used to achieve selectivity in the reduction of vinyl radicals. An increase in regioselectivity had already been observed in several reactions in which tributyltin hydride had been replaced by the more bulky tris(trimethylsilyl)silane (see **Silanes as Reducing Reagents in Radical Chemistry**).^{120,121} A far greater effect was achieved by Maruoka¹²² when he employed the bowl-shaped tin hydride TDTH [tris(2,6-diphenylbenzyl)tin hydride] (**64**)

Scheme 17 Synthesis of (*S*)-naproxene (**61**) by radical reduction with chiral trialkyltin hydride **63** in the presence of the Lewis acid magnesium bromide.¹¹⁶

	Molar ratio of Et ₃ B: 65	Reducing agent R ₃ MH	Yield 66 (%)	E/Z
1	0.2	Bu ₃ SnH	92	1:3.1
2	0.2	Ph ₃ SnH	98	1:4.3
3	1.0	(Me ₃ Si) ₃ SiH	76	1:6.7
4	1.0	TDTH	76	1:65.8

Scheme 18 Stereoselective hydrogen transfer from the bowl-shaped tin hydride **64**.¹²²

as reducing agent (Scheme 18). While the radical cyclization of iodide **65** led to a mixture of stereoisomers (*E*)- and (*Z*)-**66** when common hydrogen donors were employed (see table in Scheme 18, entries 1–3), reagent **64** reacted far more selectively (entry 4). As a matter of fact, delivery of hydrogen to the intermediate vinyl radical **67** has been achieved with far higher preference from the less hindered face.

3 FUNCTIONAL GROUP TRANSFORMATIONS

3.1 Reaction Types and Principles

Most radical reactions in which organostannanes are involved can be easily understood by a closer look at three basic steps. Exemplified for tributyltin hydride, the general chain process is shown in Scheme 19.

First arising from the initiation reaction, the tributylstannyl radical $\text{Bu}_3\text{Sn}^\bullet$ generates radicals $\text{R}^1\cdot$ by transfer of an atom or group X, or alternatively by addition of $\text{Bu}_3\text{Sn}^\bullet$ to suitable functional groups such as alkynes. The large variety of atoms and functional groups that are susceptible to organotin radicals according to phase 1 of the cycle will be presented in Section 3.3. In this context, it is important to mention that $\text{R}^1\cdot$ does not necessarily have to be a carbon-centered radical.

Once radical $\text{R}^1\cdot$ has been formed, the mechanism enters phase 2, in which the tin reagent is usually inactive. As will be shown with illustrative examples, manifold reactions have so far been developed using radicals generated by tin reagents. The main reaction types of phase 2 are intermolecular addition reactions of $\text{R}^1\cdot$ to the radical acceptors, intramolecular additions or cyclizations, rearrangements of $\text{R}^1\cdot$, and fragmentation reactions. From the modification of $\text{R}^1\cdot$ in phase 2, a new radical $\text{R}^2\cdot$ is formed, which can again be carbon- or heteroatom-centered. Only for simple reductions, which may occasionally also be desired, no reaction of radical $\text{R}^1\cdot$ should occur. The requirement that the tin hydride has to stay “inactive” to allow further conversion of $\text{R}^1\cdot$ by the above-named reaction types or combinations thereof is often only fulfilled by well-defined reaction conditions, since most organostannanes are potent hydrogen-atom donors which may as well reduce the radical $\text{R}^1\cdot$ directly.

The hydrogen-donor abilities of tin hydrides are the key properties for a successful passage through phase 3. At this point of the reaction mechanism, a hydrogen atom has to be transferred from the organostannane to radical $\text{R}^2\cdot$, which in turn furnishes the final product $\text{R}^2\text{-H}$ as well as a new “chain-carrying” or propagating tin-centered radical ($\text{Bu}_3\text{Sn}^\bullet$). More details on the hydrogen transfer are presented in Section 3.2.

Scheme 19 Three phases of tin hydride-mediated radical reactions.

Table 1 Rate constants for the reductions of different types of carbon- and heteroatom-centered radicals by tributyltin hydride and tris(trimethylsilyl)silane.¹²³

Radical	k_{SnH}	k_{SiH}
$t\text{-BuO}^\bullet$	2.0×10^8	1.1×10^8
$\text{RCH}_2^\bullet$	2.4×10^6	3.8×10^5

R, alkyl.

3.2 Hydrogen-Donor Abilities

Including such simple molecules as isopropanol as well as structurally complex substances such as vitamin E, a wide range of compounds are known to act as hydrogen donors in radical reactions. Among all commonly used reagents, tin hydrides still show comparably good properties with respect to the rate of hydrogen transfer to a wide range of carbon- and heteroatom-centered radicals (Table 1).¹²³ Not surprisingly, there are continuing efforts to develop competitive replacements that are both cheap and effective. Probably, the most prominent substitute for tributyltin hydride known today is tris(trimethylsilyl)silane (**Silanes as Reducing Reagents in Radical Chemistry**).^{120,121} Recent developments have also focused on NHC-boranes (see **Boron in Radical Chemistry**) and the reagents for the activation of water (**Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions**).

Although high rate constants for the hydrogen-transfer step from tributyltin hydride to a designated target radical $\text{R}^{2\bullet}$ may appear advantageous at first sight (Scheme 19) because undesired side-reactions of $\text{R}^{2\bullet}$ prior to phase 3

can be minimized, this property sometimes also turns out to be problematic. This is especially true for those cases in which the addition, cyclization, fragmentation, or rearrangement step in phase 2 is not particularly fast, so that the hydrogen transfer from Bu_3SnH to radical $\text{R}^{1\bullet}$ becomes a competing process to the envisaged pathway. When facing this type of complication, one countermeasure certainly is to structurally modify the participating reactants. For example, for intramolecular radical additions to alkenes, a different type of alkene may be chosen to speed up the addition step. This approach, however, is often time consuming since a number of additional reactions may be needed to get back to the originally planned synthetic route. Far easier, if applicable, is the alternative strategy to decrease the overall reducing abilities of the tin hydride by lowering its concentration. For this purpose, the tin hydride is often added to the reaction mixture slowly by a syringe pump, together with the radical initiator. An impressive example showing the positive effects of a controlled addition of the tin hydride is the cyclization of bromide **68** to the tricyclic compound **69**, which has been part of the total synthesis of the natural product (+)-cladantholide (**70**) (Scheme 20).¹²⁴ Although two primary alkyl radicals occur on the way from **68** to **69**, no remarkable reduction of those intermediates was observed, indicating that the concentration of Bu_3SnH had been sufficiently reduced.

On the other hand, also higher rates of hydrogen transfer than those reported in Table 1 can be required for some reactions. For radicals $\text{R}^{1\bullet}$ arising from phase 1 (Scheme 19), for example, which show a strong but undesirable tendency to fragment or rearrange, a very rapid reduction by the tin hydride is needed to keep the molecular structure unchanged. The goal to formally further increase

**Scheme 20** Key step in the total synthesis of (+)-cladantholide (**70**).¹²⁴

Scheme 21 Polarity-reversal catalysis by benzeneselenol (**72**) in tin hydride-mediated reductions of nucleophilic alkyl radicals.^{126,127}

the hydrogen-transfer abilities of tin hydrides can be nicely achieved by applying the principle of polarity-reversal catalysis.¹²⁵

In reactions featuring this type of catalysis, one slow polarity-mismatched step is usually replaced by two more rapid but polarity-matched steps. For the hydrogen transfer from hydric stannane **7** to nucleophilic alkyl radicals **71**, which is a polarity-mismatched reaction, Crich has found benzeneselenol (**72**) to be a well-suited additive (Scheme 21).^{126,127} Regarding the catalyzed process, the nucleophilic alkyl radical is now first reduced by the acidic (electrophilic) benzeneselenol (**72**) to give an electrophilic selenyl radical **73**, which is converted back to **72** by hydrogen transfer from the nucleophilic tributyltin hydride **7**. In this way, the reaction passes through two polarity-matched steps.

The concept of polarity-reversal catalysis can easily be understood by the polar effects shown above.^{125,127} An alternative explanation has been proposed by Zavitsas and Chatgililoglu based on repulsion energies at the transition state.^{128,129} Other examples for polarity-reversal catalysis include hydrogen-transfer reactions from silanes and germanes, which can be catalyzed by thiols.¹²⁷ An approximate idea of the increase in reaction rate can be derived from a closer inspection of Table 2.

Table 2 Reaction rates for the hydrogen transfer to primary alkyl radicals from tributyltin hydride,¹³⁰ benzeneselenol,¹³¹ thiophenol,¹³² and tributylgermanium hydride.¹³³

Reductant	<i>k</i> (s ⁻¹) at 25 °C
Bu ₃ SnH (7)	2.4 × 10 ⁶
PhSeH (72)	1.2 × 10 ⁹
PhSH	1.4 × 10 ⁸
Bu ₃ GeH	1.0 × 10 ⁵

From the fact that primary (nucleophilic) alkyl radicals are reduced 500 times faster by benzeneselenol than by tributyltin hydride, an increase in reaction rate by the factor of 25 can be expected from the use of only 5 mol% of benzeneselenol. Selected results from a study on the inhibition of the acyloxy migration (**Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**) by an accelerated hydrogen to radical **74** are shown in Scheme 22.¹²⁶

Starting from bromide **75**, the rearrangement of **74** to give **76** could not be avoided under the standard tributyltin hydride conditions. By the addition of benzeneselenol, diphenyl diselenide, or thiophenol, in contrast, a faster hydrogen transfer to radical **74** was achieved and thus far larger amounts of the non-rearranged product **78** were obtained as compared to **77**. A review on the catalysis of stannane-mediated radical chain reactions by benzeneselenol, which contains many more interesting examples, was published by Crich.¹²⁷

3.3 Functional Groups Sensitive Toward Organotin Radicals

The aim of this section is to give an overview of those functional groups that are sensitive to organotin hydrides in the sense that carbon- or heteroatom-centered radicals are generated by an attack of the organostannyl radical on the respective group.¹³⁴ The following examples have been chosen to give a more detailed insight into how phase 1 of the general mechanism (Scheme 19) can look like. Radical generation by organostannanes from suitable functional groups has by now been combined with a tremendous number of follow-up processes or applications in phase 2, which cannot comprehensively be presented in

Scheme 22 Acyloxy migration depending on the rate of hydrogen transfer.¹²⁶

this article. Nevertheless, to give an idea about the vast possibilities, we have tried to include examples showing very different subtypes of the above-mentioned five general reaction modes of reduction, cyclization, intermolecular addition, rearrangement and fragmentation. More information on which reactions are feasible in phase 2 can be found in other articles of this encyclopedia. Functional group transformations achieved by ionic reactions of tin hydrides have been reviewed by Shibata and Baba.¹³⁵

3.3.1 Radical Generation from Carbon–Halogen Bonds

Carbon-centered radicals are readily generated from many types of iodides and bromides. Owing to the relative ease of their preparation, this group of starting materials has emerged as the most popular in reactions with organostannanes. The earliest example described by van der Kerk has been shown in the introductory section (Scheme 1).¹

Scheme 23 Radical generation from alkyl bromide **79** leading into a 1,2-imino rearrangement.¹³⁶

Scheme 24 Radical generation from aryl bromide **85** as part of the synthesis of indoline **84**.¹³⁷

More recently, the treatment of alkyl bromide **79** with tributyltin hydride and AIBN led to the formation of the primary alkyl radical **80**, of which only a small part was directly reduced to **81** (Scheme 23).¹³⁶ On the major reaction pathway, **80** rearranged via cyclization to the benzylic aziridine **83**. Subsequent ring-opening and final reduction by Bu_3SnH gave **82**. Despite the ring strain, the formation of aziridine **83** can be explained by the stabilizing benzylic nature of radical **83** as well as the Thorpe–Ingold effect induced by the quaternary carbon center in **80**. This reaction also represents a first chemical example for a radical 1,2-imino rearrangement and it has been proposed as chemical model for an aminomutase.

As part of a new enantioselective approach to indoline **84**, aryl radicals have been generated from aryl bromide **85** by tributyltin hydride (Scheme 24).¹³⁷ The synthesis of **85**, which was required as starting material, was achieved by phase-transfer-catalyzed alkylation of 2-bromobenzyl bromide **86** with glycine imine **87** in the presence of the cinchonidinium salt **88**. The reaction further demonstrates that aryl chlorides are usually stable under standard radical tributyltin hydride reaction conditions.

In a recent study, the use of microreactors (see **Radical Chemistry by Using Flow Microreactor Technology**) has led to significantly accelerated reactions of tributyltin hydride and tris(trimethylsilyl)silane (Scheme 25).¹³⁸ When conducted in a continuous flow system, the cyclization of bromide **89** to indane **90** was completed in less than 1 minute, demonstrating that tributyltin

Scheme 25 Tributyltin hydride-mediated radical generation and cyclization in a microreactor.¹³⁸

hydrides are well compatible with this new technology.

The ability of tributyltin hydride and AIBN to selectively generate radicals from more complex reactants became obvious from the tandem reaction starting from alkyl iodide **91** (Scheme 26).¹³⁹ Via cyclization of the alkyl radical onto the aziridinyl imine moiety and a unique fragmentation mechanism including the intermediates **92** and **93**, cyclohexyl radical **94** was formed. Subsequent intramolecular radical addition to the azido group (**Unusual Radical Acceptors**) was followed by a loss of nitrogen and a reduction of the aminyl radical to a secondary amine **95**. For the purpose of isolation, the amine was converted to sulfonamide **96**.

The versatile concept of tin hydride-mediated aryl radical generation from aryl iodides was used for a transfer of axial chirality to centrochirality by a 5-exo-type cyclization. In one of the reactions reported by Curran (Scheme 27), indolone **97** was obtained from acrylanilide **98** in high yield and with a high degree of chirality transfer.^{140,141}

Very recent applications of aryl iodides as radical precursors include syntheses of penitremes¹⁴² and of natural products such as acutumine.^{143,144} While in

Scheme 26 Radical generation from alkyl iodide **91** combined with intramolecular cyclizations onto imine and azide moieties.¹³⁹

Scheme 27 Aryl radical generation from aryl iodides for the purpose of chirality transfer.^{140,141}

the case of bromides or iodides the generation of carbon-centered radicals is practically independent of the nature of the carbon atom, remarkable differences are observed when organochlorides are employed as the radical sources. A pioneering study in this field that already gave evidence for these effects was reported by Kuivila *et al.*¹⁴⁵

From activated positions, such as polychlorinated carbon atoms, α -positions of esters and ketones, captodatively substituted carbon atoms, or benzylic positions, the chlorine atom transfer to the organostannyl radical still proceeds sufficiently fast. Acyl radicals can be generated from acid chlorides, but this is done preferably in the presence of samarium reagents (see **Organic Synthesis Using Samarium Diiodide**).¹⁴⁶ Non-activated alkyl chlorides usually react slowly, whereas aryl and vinyl chlorides tend to be stable under common reaction conditions. An example featuring the Bu_3SnH -mediated 5-endo radical cyclization of α -halogenated amides is shown in Scheme 28.¹⁴⁷ In this special case, the cyclization of α -chloro amide **99** to the bicyclic amide **100** proceeded significantly smoother than that of the corresponding α -iodo derivative **101**, which mainly led to the non-cyclized but reduced product **102**. A more detailed investigation revealed that this effect is probably due

Scheme 28 Comparative study on the cyclization of radicals generated from α -haloamides **99** and **101**.¹⁴⁷

Scheme 29 Reaction cascade leading from chloride **103** to the unsaturated piperidine **104**.¹⁴⁹

to differences between the initial conformations of the α -halo amides **99** and **101** and the respective radicals. The ability of the α -iodo derivative **101** to undergo the cyclization could finally be restored by adding Bu_3SnCl or Bu_3SnF to the reaction mixture. A recent study on comparable cyclizations of α -halo amides has been reported by Curran.¹⁴⁸

An interesting transformation of azetidinone **103** was observed when the compound was treated with tributyltin hydride and AIBN (Scheme 29).¹⁴⁹ Owing to the fact that a comparatively well-stabilized carbon-centered radical **105** occurs as first intermediate opens up the option to use an α -chloro glycine derivative as precursor. Via one cyclization and two ring-opening steps, radical **105** was subsequently converted to a structurally unique piperidine **104**. The yield of product **104** has most probably to be attributed to its relatively low stability under the reaction conditions applied.

An overview over radical cyclization reactions that contains many more examples on related tinhydride-mediated processes has been reported by Giese.¹⁵⁰ Tin hydride-mediated reactions of polychlorinated substrates in which radicals are selectively generated by the abstraction of chlorine atoms located in activated positions have already been developed.¹⁵¹ From trichloromethane groups, the first chlorine atom is far more easily removed by the tributyltin radical than the remaining halogen substituents. An example taking advantage of this effect is shown in Scheme 30.^{152,153}

Scheme 30 Cyclization of **106** via radical generation from a trichloromethyl group.¹⁵²

Under standard tributyltin hydride conditions, the trichloromethyl-substituted cyclohexylamine **106** was converted to the spirocyclic product **107**. For a complete dehalogenation of dichloromethylene units, such as the one present in **107**, reaction times have to be prolonged and excess tributyltin hydride has to be applied.

The ability of Bu_3SnH to differentiate between aryl chlorides and bromides has previously been shown in Scheme 24. Given that the halogen atoms are located at a comparably activated carbon atom, the overall rate for an abstraction by tributyltin hydride decreases in the order iodides > bromides > chlorides. The gap arising from the inability of tin hydrides to generate aryl radicals from aryl chlorides can be closed by employing a common substitute for Bu_3SnH , that is, tris(trimethylsilyl)silane.^{120,121} Under very high pressures, reductions of organic chlorides by tributyltin hydride even proceed in the absence of radical initiators.¹⁵⁴

3.3.2 Radical Generation from Carbon–Carbon Bonds: Radical Decarboxylations

A suitable strategy to achieve the cleavage of terminal alkyl carbon–carbon bonds is radical decarboxylation reactions. For the generation of the usually short-lived carboxyl radicals, which readily fragment carbon dioxide, *O*-acyl-thiohydroxamates (Barton esters, Pyridine-2-thione-*N*-oxycarbonyl (PTOC) esters) have emerged as well-known precursors over the last decades. The first report on this compound class by Barton dates back to 1983.¹⁵⁵ Barton esters **108** usually decompose via the homolytic cleavage of the nitrogen–oxygen bond in the hydroxamate, which can be induced by irradiation, by heating, or by application of standard radical initiators (Scheme 31). In the presence of reducing agents such as organotin

hydrides, a hydrogen atom is then transferred to the carbon (or heteroatom) centered radical arising from the decarboxylation step.^{156–161} The most common method for the preparation of Barton esters with the general structure **108** relies on the coupling of activated carboxylic acids **109** to *N*-hydroxy thiopyridone **110**.¹⁶² Below, a recent example is depicted, in which Barton esters **111** were reductively decarboxylated under various conditions to give *cis*-substituted cyclopropanes **112**.^{163,164} The final products **113** of the synthetic study were designed as conformationally restricted analogs of the antipsychotic haloperidol.

By employing Barton esters in combination with different types of radical scavengers, a large variety of functional group transformations can be achieved, which is by far not limited to simple reductive decarboxylations. An informative recent review on this topic has been provided by de Almeida.¹⁶²

Reductant	Initiator	Solvent	Temperature (°C)	Yield 112 (%)	<i>cis/trans</i> 112

3.3.3 Radical Generation from Carbon–Nitrogen Bonds

For the generation of carbon-centered radicals by an organostannyl-induced cleavage of carbon–nitrogen bonds, two functional groups have been found particularly useful (Scheme 32). The first report on the tributyltin hydride-mediated reduction of isocyanides (see **Unusual Radical Acceptors**) appeared in 1968.¹⁶⁵ The behavior of nitro groups under comparable conditions was first investigated by Ono and reported in 1981.¹⁶⁶ Both reaction types can be rationalized by an addition of the organostannyl radical onto the isonitrile **114** or nitro group **115** and a subsequent carbon–nitrogen bond cleavage leading to the desired carbon-centered radical.

The methodology involving isonitriles has so far successfully been used for the reductive deamination of steroids, carbohydrate derivatives, and amino acids.^{167–169} While all types of aliphatic isonitriles are cleanly reduced, aromatic derivatives tend to be stable. An impressive example in which the selective removal of one out of four amino groups was achieved from a disaccharide is depicted in Scheme 33.¹⁶⁹ The differentiation among the amino groups was possible due a selective conversion of a tetraformamide to (mono-)isonitrile **116**, which gave **117** upon treatment with tributyltin hydride and AIBN.

Tin hydride-mediated formation of carbon-centered radicals from organic nitro compounds is slightly more limited in its scope than the isonitrile methodology presented earlier. Nitro groups are usually only then smoothly transferred to organotin radicals when tertiary or better stabilized carbon-centered radicals arise from this step.^{170,171} In a preparative study, tin hydride-mediated radical denitration has been employed as part of a sequence leading from [2 + 3] cycloadducts **118** of nitroalkenes **119** and camphor-derived oxazoline-*N*-oxides **120** to denitrated tetracycles **121** and aldol-type products **122** (Scheme 34).¹⁷²

The denitration methodology has been further applied in the synthesis of kainic acid derivatives¹⁷³ as well as for the stereoselective preparation of *C*-glycosides taking advantage of the anomeric effect.¹⁷⁴ A denitration procedure catalytic in tin hydride, employing phenylsilane as regenerating agent, was reported by Fu.¹⁷⁵

The generation of secondary carbon-centered radicals already requires harsher conditions, and primary alkyl radicals have so far not been accessible from nitro compounds by using tin hydride reagents.^{176–178} When applied to the reduction of aromatic nitro compounds, organostannanes usually lead to the undesired formation of anilines.^{40,166} Nevertheless, to achieve the cleavage of carbon–nitrogen bonds in which the carbon atom is

Scheme 32 Tin radical-mediated cleavage of carbon–nitrogen bonds from isonitriles **114** and nitro compounds **115**.^{165,166}

Scheme 33 Radical deamination of disaccharide **116** by tin hydride-mediated cleavage of an isonitrile.¹⁶⁹

part of an aromatic system, arenediazonium salts have been found as suitable precursors in combination with tin hydrides.¹⁷⁹ A review on the reductive cleavage of aliphatic nitro groups, which also includes many examples from ionic chemistry, was published by Ono.¹⁸⁰

3.3.4 Radical Generation from Carbon–Oxygen Bonds

As mentioned in the introduction, the development of Barton–McCombie deoxygenation reactions in the 1970s represented a major advance not only in radical chemistry but in the whole field of organic chemistry (Scheme 2).² For the first time, carbon–oxygen bonds could be cleaved under comparably mild conditions, and carbon-centered radicals were available from alcohols by the simple strategy of converting them to xanthates (or dithiocarbonates).^{159,181} Exemplified for the tributyltin radical, the underlying mechanistic principle of the deoxygenation protocol is shown in Scheme 35.^{182,183} In the first step, adduct **123** is

reversibly formed from the addition of a stannyl radical to xanthate **124**. Taking advantage of the fact that the undesired carbon–sulfur bond cleavage is slow due to the reactivity of the methyl radical potentially arising from this process (A), the overall reaction pathway can be directed towards the scission of the carbon–oxygen bond (B). In its simplest version, the carbon-centered radical **125** is then reduced by hydrogen transfer from tributyltin hydride, while the stannyl dithiocarbonate **126** further decomposes to carbon oxysulfide and the stannyl thioether **127**.

Owing to the structure of the xanthate and the reaction conditions that were applied, the early deoxygenation protocols gave the best results for secondary alcohols. The xanthates of tertiary alcohols, which are likely to decompose through the Chugaev elimination, were later deoxygenized under milder conditions, preferably at lower temperatures.¹⁸⁴

In the case of xanthates derived from primary alcohols, the selectivity in the fragmentation step (**123** → **125/126**) is no longer well defined since primary carbon-centered radicals are

Scheme 36 Barton–McCombie deoxygenations in synthetic studies toward (–)-nakadomarin A (**130**)¹⁸⁹ and pumiliotoxin C.¹⁹⁰

formed from both types of bond cleavage A and B (Scheme 35). To circumvent this problem, modified thiocarbonyl compounds have been developed, such as thiocarbonyl imidazolides^{159,185} and *O*-aryldithiocarbonates,^{186–188} which show a far more distinct preference towards the cleavage of the carbon–oxygen bond once they have been converted to adducts of type **123**.

Two recent examples from the field of natural product synthesis are shown in Scheme 36. The tetracyclic core of *ent*-nakadomarin A **128** was prepared according to the classical Barton–McCombie protocol, in which tributyltin hydride was used to reduce a xanthate previously obtained from a secondary alcohol **129** upon treatment with sodium hydride, carbon disulfide and methyl iodide.¹⁸⁹ The manzamine-related marine alkaloid (–)-nakadomarin A (**130**) represents an interesting target because of its cytotoxic and antimicrobial activity.

The efficacy of a new cycloaddition approach to pumiliotoxin alkaloids **131** was demonstrated by Fearnley.¹⁹⁰ In the final steps of the synthesis, alcohol **132** was cleanly converted to target compound **133** by a modified Barton–McCombie procedure using the imidazolyl-thiocarbonyl derivative **134**. Further examples for the application of tin

hydride-mediated radical deoxygenation reactions that have recently appeared in literature include the syntheses of calystegine A3,¹⁹¹ (*S*)-dapoxetine,¹⁹² and (+)-makassaric acid.¹⁹³

3.3.5 Radical Generation from Carbon–Sulfur and Carbon–Selenium Bonds

The most commonly used functional groups for the generation of radicals by homolytic cleavage of carbon–sulfur or carbon–selenium bonds are thio- and selenoethers as well as xanthates. Already in early studies, the phenylsulfides,^{194,195} xanthates (see **Xanthates and Related Derivatives as Radical Precursors**),¹⁹⁶ and phenylselenides^{197,198} were not just reduced by hydrogen transfer in the presence of tin hydrides but also employed for carbon–carbon formations. More recently, thioethers appeared as intermediates in organotin hydride-catalyzed radical desulfurizations of thionoesters and thionolactones¹⁹⁹ as well as in syntheses of carbohydrates.²⁰⁰ As part of the preparation of isoadenosine **135**, thioether **136** was cleanly reduced by tributyltin hydride to give **137** (Scheme 37).²⁰¹

Scheme 37 Radical generation from thioether **136**,²⁰¹ bis-xanthate **139**,²⁰² and selenoether **141**.²⁰³

Further demonstrating the vast possibilities of radical xanthate transfer chemistry, a new way of access to spiroketal **138** has been developed by Zard.²⁰² The reductive removal of two xanthate functionalities from **139** to give **140** was possible by either combining dilauroyl peroxide and isopropanol or tributyltin hydride and AIBN. A recent report on the use of phenyl selenides as radical sources focuses on the synthesis of tetrahydrofurans.²⁰³ Starting from selenoether **141**, the carbon-centered radical **142** arising from the selenophenyl group transfer was found to cyclize onto an aldehyde to give oxygen-centered radicals **143**, which were further reduced by Bu_3SnH to the final product **144**. Moreover, selenoesters have been shown to be convenient precursors for acyl radicals.²⁰⁴

3.3.6 Radical Generation by Addition of Tin Radicals to Unsaturated Systems

In contrast to the examples presented up to this point (Sections 3.3.1–3.3.5), in which the generation of radicals was achieved by atom or group transfer reactions to organostannyl radicals, carbon-centered radicals are also available from the addition of tin-centered radicals to unsaturated systems such as isonitriles, alkynes, and carbonyl compounds.

While aliphatic isonitriles are suitable precursors for tin-mediated radical deamination reactions (see Section 3.3.3), their aromatic counterparts do not decompose in the same way once they have formed an adduct with organostannyl radicals. Instead, the

Scheme 38 Indole synthesis proceeding via α -stannoimidoyl radical **146**.²⁰⁶

α -stannoimidoyl radical adducts can be used for cyclization reactions. Pioneering work in this field, in which the special feature of aromatic isonitriles was exploited for a novel synthetic access to indoles, has been presented by Fukuyama (**Unusual Radical Acceptors**).²⁰⁵ An example from a recent application of the methodology is depicted in

Scheme 38.²⁰⁶ Addition of a tributyltin radical to isonitrile **145** led to the α -stannoimidoyl radical **146**, which cyclized onto the proximate acrylate moiety. The stannylated indole **147** obtained from hydrogen transfer to **148** was further converted by Stille-type cross-coupling reaction with aryl iodide **149** to yield indole **150**.

Scheme 39 Tin hydride-mediated synthesis of acrylamide **157** from alkyne **152**, carbon monoxide, and diamine **154**.²¹¹

Acetylenes are well-known acceptors for organostannyl radicals, and a large number of reactions has meanwhile been developed taking advantage of this efficient process. Hydrostannylations, which represent the simplest type of reactions exploiting this principle, can be conducted either in the form of radical^{7,207} or transition-metal-catalyzed processes.^{208–210} As shown in Scheme 39, the highly reactive vinyl radical **151** emerging from the addition of the tributylstannyl radical to alkyne **152** is able to react with carbon monoxide to give α -ketenyl radicals **153**.²¹¹ Trapping of **153** by amine **154** is followed by tautomerization to **155** and 1,4-*H* migration to produce α -keto radical **156**, which finally fragments to acrylamide **157**. Since the tributyltin radical is regenerated in the last step of the cycle, the reaction proceeds with substoichiometric amounts of the reagent.

Further examples in which the tributyltin radical is liberated in the final stage of the reaction and which can thus be conducted catalytically in

tin hydride can be found in the literature.²¹² In case the tributyltin moiety remains as a substituent on the alkene, it can either be cleaved by protodestannylation,²¹³ or be used as a precursor for Stille cross-coupling reactions (Scheme 38).

The fact that *O*-stannylketyl or related radicals are reversibly formed in more or less small amounts from tin-centered radicals and carbonyl compounds only becomes obvious when an effective further reaction pathway exists for respective stannylketyl radicals.^{214–217} Even ester functionalities, which are generally not susceptible to tin-centered radicals and which therefore remain unchanged in most radical reactions involving organostannanes, can play a role as tin radical acceptors when the above-mentioned requirement is fulfilled. An example from a recent investigation in this field is shown in Scheme 40.²¹⁸ Treatment of ester **158** with catalytic amounts of tributyltin chloride in the presence of PMHS and potassium fluoride gave **159** via the fragmentation

Scheme 40 Tin hydride-induced radical fragmentation of ester **158**.²¹⁸

Scheme 41 Synthesis of 2,3-disubstituted indole **168** via the allylic *O*-stannylketyl radical **164**.²²⁸

of the *O*-stannylketyl radical **160**. The pyrimidine-sulfonyl radical **161** liberated in the fragmentation step regenerates $\text{Bu}_3\text{Sn}^\bullet$ from Bu_3SnH and forms aryl sulfinic acid **162**. Acid **162** is necessary for the further protolysis of tin enolate **163** to give **159**.

The first examples for the tributyltin hydride-induced formation of *O*-stannylketyl radicals in cyclization reactions of aldehydes and ketones to alkenes were reported by Enholm.^{219–222}

The general reaction principle was since expanded to various substrates.^{223–227}

A new synthetic access to indoles proceeding via the formation of allylic *O*-stannylketyl radicals has recently been discovered by Kim (Scheme 41).²²⁸ In the underlying reaction mechanism, the allylic stannylketyl radical **165** derived from **164** is converted to an aryl radical **166** via loss of nitrogen from the benzotriazol moiety. Cyclization of **166** onto the *O*-stannyl enolate and further reduction by tributyltin hydride led to an intermediate tin alcoholate **167**, which transformed to the 2,3-disubstituted indole **168** by hydrolysis and cleavage of acetaldehyde (**169**).

3.3.7 Generation of Heteroatom-Centered Radicals

The group of nitrogen-centered radicals can be divided into the three major subtypes: aminyl, iminyl, and amidyl. Figure 3 shows a collection of precursors that have so far been successfully used in combination with organostannanes. More exactly, the bond cleavage indicated can generally be induced by an attack of a tin-centered radical on the bold-printed atom of the functional group attached to the nitrogen atom which is to be transformed into a radical. The simplest precursors for aminyl radicals are *N*-chloroamines **170**.^{229,230} Via a nitrogen–nitrogen bond cleavage, aminyl and iminyl radicals have been generated from azides **171**,^{231,232} benzotriazoles **172**,²³³ thiosemicarbazones **173**,²³⁴ and dithiosemicarbazones **174**.²³⁵ Further precursors that give radicals after nitrogen–oxygen bond scission are iminoxymethyl selenides **175**,²³⁶ oxime benzoates **176**,²³⁷ and *N*, *O*-diacyl hydroxylamines **177** and **178**.^{238,239} Nitrogen-centered radicals can finally be formed via homolysis of N–S bonds. Suitable starting materials for this strategy are

Figure 3 Precursors for the generation of nitrogen-centered radicals via an attack of $\text{R}_3\text{Sn}^\bullet$ at the bold-printed atoms followed by fragmentation and/or group transfer.

Scheme 42 Key steps from the synthesis of (±)-13-deoxyserratine.²⁴⁵

sulfenamides **179**,²⁴⁰ *N*-acyl sulfenamides **180**,²⁴¹ iminothio benzothiazoles **181**,²⁴² or thiooximes **182**.^{243,244}

By applying one of the above-shown precursors, a short synthetic access to (±)-13-deoxyserratine (**183**) could be developed (Scheme 42).²⁴⁵ In the presence of tributyltin hydride and ACCN, *O*-benzoyl-*N*-allylhydroxamate **184** was first converted to amidyl radical **185**, which gave **186** after two consecutive cyclization steps and reduction by Bu₃SnH. It is interesting to note that the chlorine atom, which had to be placed on the allyl chain to achieve the desired 6-endo mode in the second cyclization step, was selectively removed by the excess Bu₃SnH after completion of the cyclization sequence. The reaction pathway is fully comprehensible when bearing in mind that tin hydrides

are usually unable to reduce aromatic or vinylic chlorides (such as in reactant **184**), while aliphatic chlorides are generally sensitive to the reagent (see also Section 3.1.1).

More detailed information on recent progress in the generation and use of nitrogen-centered radicals, including many examples and alternative tin-free methods, can be found in a review article by Zard.²⁴⁶

In comparison to nitrogen-centered radicals, their oxygen-centered analogs are more often generated from labile hypobromites or hypoiodites under photochemical initiation than by atom or group transfer to tin-centered radicals. An interesting and comprehensive review on developments in this field of radical chemistry has been published by Hartung.²⁴⁷

Figure 4 Precursors for the generation of oxygen-centered radicals via an attack of R₃Sn[•] at the bold-printed atoms followed by fragmentation and/or group transfer.

Scheme 43 Radical cyclization of oxyl radical **196** generated from nitrate **195**.²⁴⁸

A compilation of those precursors that have successfully been used for the generation of oxygen-centered radicals in combination with tin hydrides is shown in Figure 4. Regarding the mechanisms along which oxyl radicals are formed from nitrates **187**,²⁴⁸ thiopyridones **188**,^{249,250} phthalimides **189**,²⁵¹ thiazolthiones **190**,²⁵² dithiocarbamates **191**,²⁵³ selenoimines **192**,²⁵⁴ and sulfonates **193**,²⁵⁵ the cleavage of a nitrogen–oxygen bond represents the most common key step.

Similar to the generation of nitrogen-centered radicals, the fragmentation of the respective radical oxyl precursors **187–193** is induced by an attack of a tin-centered radical on the functional groups on the right side of the waved bonds (Figure 4). The cyclization of nitrate **194**, leading to the bicyclic product **195**, therefore starts with an attack of the $\text{Bu}_3\text{Sn}^\bullet$ radical on the nitrate moiety.²⁴⁸ Subsequent formation of tributyltin nitrite ($\text{Bu}_3\text{Sn}-\text{ONO}$) liberates the oxyl radical **196**, which converts to **195** via cyclization to **197** and reduction (Scheme 43).

4 CONCLUSIONS

Although the examples presented in this article can only give a shallow insight into the field of tin hydride-mediated radical reactions, we hope that we have nevertheless been able to illustrate the vast possibilities associated with this type of reagents. Most importantly, significant advances have been made in recent years concerning the development of new organotin reagents that are easy to separate during work-up. Hopefully, the traditional reagents such as tributyltin hydride will be more and more replaced by new inventions in the coming years, since this evolution might then finally change the long-standing reluctance of many organic chemists toward radical tin hydride chemistry.

1 INTRODUCTION

When photochemical reactions are applied to organic synthesis,^{1–4} they are often per se designed as radical reactions. However, many photochemical transformations^{5,6} do not belong to this category. Photochemically performed pericyclic reactions are typical examples. In many other cases, intermediates are involved which possess only “partial” radical character, for instance, when singlet “biradicals” are generated. Such transformations are not discussed in this article. On the other hand, a large variety of free radical species are generated with photochemical reactions. Molecules change their electronic configuration when they are photochemically excited. Consequently, the chemical reactivity is significantly modified. For instance, an electron transfer may be facilitated or the bond energy is reduced in a way that homolytic bond cleavage leads to radical species. Both processes are frequently applied in radical chemistry. In such cases, usage of additional reagents such as radical starters is often avoided and thus the amount of side products is diminished. Photons are then considered as traceless reagents. In this context, photochemical reactions are frequently classified as sustainable methods.

Many applications of organic synthesis have been reported. In this article, we have presented a very limited number of examples. A certain preference is given to reactions that are applied to multistep synthesis.

2 PHOTOCHEMICAL ELECTRON TRANSFER-INDUCED RADICAL REACTIONS

2.1 Metal-Free Induced Reactions

The redox potentials of molecules change completely when they are electronically excited.^{7–9} In most cases, electron transfer is facilitated and the redox chemistry of organic compounds is considerably enriched. Photochemical electron transfer is also a suitable method to generate radical intermediates. In such cases, a radical ion pair is formed. Radical ions possess a broad reactivity spectrum that may be applied in targeted ways to organic synthesis.^{10,11} Frequently, such a radical ion pair undergoes an acid–base reaction to generate neutral radicals. This process may occur when electronically excited, C₆₀ fullerene oxidizes tertiary amines, as described for the alkaloid scandine (Scheme 1).¹² In the resulting radical ion pair **1** and **2**, a proton exchange occurs and leads to the neutral radicals **3** and **4**. Radical combination now leads to the intermediate **5**. A further intramolecular sequence of electron and proton transfer followed by radical coupling generates a second C–C bond between the fullerene and scandine. Two regio-isomers **6** and **7** are thus obtained. Under the reaction conditions, isomer **7** undergoes a [2 + 2] photocycloaddition leading to the second final product **8**, possessing four C–C bonds between the fullerene and the scandine moieties. Further alkaloids such as

Scheme 1 Photochemical electron transfer-induced radical addition of the alkaloid scandine to C_{60} fullerene.

tazettine of gramine have been transformed in the same way.

The reaction was applied to the cyclization of oligopeptides.¹³ In the case of the tripeptide **9** (Scheme 2), an electron transfer occurs between the carboxylate function and the phthalimide group (**10**).¹⁴ After elimination of CO_2 and protonation of the resulting radical anion **11**, the neutral diradical **12** is obtained. Finally, macro-cyclization occurs via radical combination which leads to the final cyclopeptide **13**. The compound resembles cyclosporine which possesses immunosuppressive activity. Similar compounds have been obtained in

photochemical electron transfer reactions involving tertiary amines which have been oxidized to radical cations.¹⁵ In such cases, trialkylsilyl substituents can be used as leaving groups to generate a neutral α -aminoalkyl radical.

This strategy was applied to the synthesis of structural analogs to the natural iminosugar nojirimycin possessing α - and β -glucosidase inhibitor activity (Scheme 3).¹⁶ 1-Deoxynojirimycin and analogs are interesting in this context due to their increased stability. The photochemical key step starts with the oxidation of the silylated tertiary amine moiety in **14**

Scheme 2 Photochemical electron transfer-induced radical macro-cyclization of phthalimide derivatives. Application to the synthesis of cyclopeptides.

Scheme 3 Intramolecular addition of silylated tertiary amines to alkynes.

by the electronically excited sensitizer dicyanophthalene. The 6-*endo*-dig cyclization of the radical cation **15** is affected by the β -silicon effect.^{17–19} The removal of the trimethylsilyl substituent from intermediate **15** during cyclization is facilitated by the presence of 2-propanol in the reaction mixture. This

effect is linked to the affinity between the silicon and oxygen atoms.²⁰ The final product **17** is obtained by trapping of the vinyl radical **16** by hydrogen transfer from 2-propanol. The bicyclic compound **6** has been transformed into a variety of structural analogs of nojirimycin such as **18**, **19**, **20**, or **21**.

Scheme 4 Photochemical electron transfer-induced radical addition of simple tertiary amines. Application to the synthesis of pyrrolizidine alkaloids and surfactants.

Photochemically generated radical ion pairs may undergo proton exchange which leads to the formation of neutral radicals. Such steps are involved in the addition of tertiary amines to electron-deficient alkenes. When aromatic ketones such as 4,4'-dimethoxybenzophenone **22** are electronically excited, they are capable of

oxidizing tertiary amines such as **23**, which leads to the formation of a radical ion pair **24** and **25** (Scheme 4).²¹ In an acid–base reaction, the neutral radical intermediates **26** and **27** are obtained. The nucleophilic α -aminoalkyl radical **27** easily adds to the electron-deficient alkene **28** and the oxoallyl radical **29** is thus generated. Hydrogen abstraction

of *N*-methylpyrrolidine **23** leads to the final product **30a,b** as a mixture of diastereoisomers. This step is part of the radical chain reaction which was identified by a product quantum yield of 4. Alternatively, the oxoallyl radical **29** may react with the ketyl radical **26**. Thus, the sensitizer **22** is easily regenerated and becomes an efficient photocatalyst.²² Concerning stereoselectivity, it should be pointed out that the radical attack occurs exclusively anti with respect to the alkoxy substituent in **28**. However, the configuration of the chiral center in the α -position of the nitrogen was not controlled. The adducts **30a** and **30b** have been separated by chromatography. They were transformed into the pyrrolizidine alkaloids (+)-laburnine and (–)-isoretronecanol, respectively.²³ Less reactive tertiary amines such as **31** can also be transformed when thiocarbonyl compounds such as **32** are added to the reaction mixture.²⁴ Such additives affect the complex interplay of different neutral radical intermediates,²⁵ as it is also observed in the case of reversible addition-fragmentation chain transfer (RAFT) polymerization (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).²⁶ The resulting adduct **34** from the transformation of furanone **33** have been transformed into zwitterion-type surfactant **35**.²⁷

Ketyl radicals that are generated by photochemical electron transfer from tertiary amines to an electronically excited ketone may also add to alkenes. The intramolecular version of this reaction was applied to the synthesis of polycyclic compounds such as alkaloids. Such ketyl radicals also induce rearrangements of polycyclic structures.²⁸

2.2 Ruthenium-Mediated Photocatalysis

As pointed out before, the use of an electron transfer with a molecule at an electronically excited state to generate a reactive radical intermediate is a widely recognized strategy in organic photochemistry. In the past decades, the use of organic sensitizers in photoinduced electron transfer reactions has been extensively studied,²⁹ and in some cases, a photoredox catalytic cycle can be achieved when sensitizers are regenerated in the course of the reaction.^{21,22,29} In contrast, the use of organometallic compounds as efficient sensitizers has been recognized only recently.³⁰ Indeed, organometallic compounds such

Figure 1 Structure of $[\text{Ru}(\text{bpy})_3]^{2+}$ complex.

as the well-known tris(2,2'-bipyridine)ruthenium(II) ion $[\text{Ru}(\text{bpy})_3]^{2+}$ can be considered as a privileged photosensitizer for several reasons (Figure 1).

Its absorption spectrum exhibits a strong broad band centered at 450 nm. Irradiation of a solution of this compound with visible light leads to a triplet excited state in which a metal-centered electron is promoted to the π^* -orbital of the bipyridyl ligand (metal to ligand charge transfer transition). This photoexcited state can behave as either an electron donor or an acceptor to produce $[\text{Ru}(\text{bpy})_3]^{3+}$ or $[\text{Ru}(\text{bpy})_3]^+$, respectively. A reductive or oxidative catalytic cycle can be envisaged based on these different redox states (Figure 2). Photoredox properties of $[\text{Ru}(\text{bpy})_3]^{2+}$ associated with its excellent chemical stability have been extensively exploited in the design of photo-responsive supramolecular devices³¹ and systems for conversion of solar energy.³²

In the field of synthetic organic photochemistry, several research groups have made significant breakthroughs since 2008. The formal $[2 + 2]$ intramolecular cycloaddition of enone **36** photocatalyzed by $[\text{Ru}(\text{bpy})_3]^{2+}$ has been studied (Scheme 5).³³ It was previously reported that such a reaction could be induced by mono-electronic reduction of an enone both chemically and electrochemically,^{34–36} affording a nucleophilic radical anion intermediate.

In this photocatalytic approach, a sacrificial amount of *i*-Pr₂NH is used as an electron donor to generate an Ru(I) complex from the electronically excited Ru(II)* species. Reduction of the Lewis acid-activated enone **38** produces the radical anion **39**, regenerating Ru(II) in the ground state. Subsequent conjugate radical addition produces intermediate **40**, which is further oxidized to give the formal $[2 + 2]$ cycloaddition product **37** (Scheme 6).

Figure 2 Reductive (a) and oxidative (b) catalytic cycle in $\text{Ru}(\text{bpy})_3^{2+}$ photochemistry.

Scheme 5 Formal intramolecular photocatalytic [2 + 2] cycloaddition of an enone.

Scheme 6 Proposed mechanism for the formal intramolecular photocatalytic [2 + 2] cycloaddition of an enone.

Notably, a formal cross $[2 + 2]$ cycloaddition between an aromatic **41** and an aliphatic acyclic enone **42** can be achieved using this optimized reaction. The reaction occurs by selective mono-electronic reduction of the aromatic enone by an Ru(I) complex (Scheme 7).³⁷ Compound **44** is obtained in 85% yield by coupling of the resulting radical intermediate **43** with aliphatic enone **42**.

Scheme 7 Formal intermolecular photocatalytic $[2 + 2]$ cycloaddition.

Scheme 8 Formal intramolecular $[2 + 2]$ cycloaddition of electron-rich alkenes.

Scheme 9 SOMO activation in organocatalysis.

Scheme 10 Asymmetric α -alkylation of an aldehyde by organophotocatalysis.

produce an Ru(III) complex.⁴⁰ Ru(III) is then able to oxidize the electron-rich alkene **45** to produce a radical cation intermediate **46** and regenerate an Ru(II) species. Compound **48** was obtained by a reductive cascade reaction. Notably, only 15 mol% of MV²⁺ was necessary, probably indicating that the radical intermediate **47** is involved in the Ru catalytic cycle by oxidation of either Ru(II) to Ru(III) or (MV⁺) to (MV²⁺).

In contrast to reactions involving organic sensitizers such as 9,10-dicyanoanthracene,^{41,42} with this methodology, high yields of cycloadducts can be obtained in short reaction time using a standard household light bulb.

In 2007, a new catalytic mode in the field of asymmetric organocatalysis called *single occupied molecular orbital (SOMO) activation* was introduced. In this strategy, the formation of a transient 3 π -electron radical can be achieved from an enamine intermediate using a single-electron oxidant (Scheme 9).⁴³

The introduction of a radical intermediate in an organocatalytic cycle considerably increases the scope of organocatalysis, allowing transformations that cannot be achieved using traditional enamine and iminium catalysis (e.g., asymmetric α -allylation, arylation, and enolation

of the aldehyde). In a continuous effort to develop new organocatalytic methodology, an organo-photocatalysis strategy by coupling a reductive Ru photocatalytic cycle and an organocatalytic cycle involving the formation of an enamine intermediate were described.⁴⁴ This methodology allowed the direct asymmetric α -alkylation of an aldehyde, a long-standing elusive goal in the field of organocatalysis (Scheme 10).

A detailed mechanism was proposed after careful investigation of the reaction. In contrast to SOMO activation, a 3 π -electron radical **54** is not involved in the productive reaction step, even if it is probably produced by oxidation of a small sacrificial amount of enamine intermediate **53** by an Ru(II) excited state, thereby initiating the Ru catalytic cycle (Scheme 11).

This resulting Ru(I) species then induces reductive cleavage of the C–Br bond of the bromoketone derivative **51** (Scheme 12) to form α -ketoalkyl radical **55**. The organocatalytic cycle begins with condensation of imidazolidinone catalyst **50** and aldehyde **49**. The resulting electron-rich enamine **53** is able to react with the electron-deficient α -ketoalkyl radical **55** to form the chiral α -aminoalkyl radical **56**. The convergence of the two catalytic cycles then occurs by single-electron transfer between the α -aminoalkyl

Scheme 11 Initiation of ruthenium catalytic cycle.

Scheme 12 Proposed catalytic cycles for the asymmetric α -alkylation of an aldehyde.

radical **56** and the Ru(II) compound at its excited state to produce an iminium ion **57** and generate the Ru(I) species. The organocatalytic cycle is completed by hydrolysis of the iminium ion **57** to produce the chiral aldehyde **52** and regenerate the amine catalyst **50**.

The interconnection of the two catalytic cycles not only avoids the use of a stoichiometric amount of a sacrificial electron donor to generate Ru(I)

species but also gives an opportunity to increase the scope of the methodology. Indeed, fine-tuning of both the stereoelectronic properties of the organocatalyst and the photoredox behavior of the Ru complex can be adjusted independently.

Several useful synthetic organic transformations based on the reactivity of the radical formed by reductive cleavage of the C–Br bond, using a ruthenium photocatalytic cycle, were introduced

Scheme 13 Photocatalytic formation of a radical by reductive cleavage of the C–Br bond.

Scheme 14 Photocatalytic reduction of an alkyl halide.

(Scheme 13). In most cases, an excess of sacrificial tertiary amine was used to afford an Ru(I) species from an electronically excited Ru(II) compound (Scheme 13).

This methodology allows the selective and mild reduction of alkyl halides, reaction that typically requires trialkyltin hydride and azobis(isobutyronitrile) (AIBN) as a radical initiator. In optimized conditions, 1 mol% of $[\text{Ru}(\text{bpy})_3]^{2+}$, 10 equiv of diisopropylethylamine, and 10 equiv of formic acid are used.⁴⁵ A typical example is shown in Scheme 14.

Mechanistic studies suggest that a formate diisopropyl ammonium radical species plays the role of a hydrogen donor in the hydrogen abstraction step. These mild reduction conditions allow selective reduction of α -alkyl halides to electron withdrawing groups. Moreover, these conditions tolerate the presence of a wide range of functional groups, including free hydroxy groups, esters, olefins, and alkynes as well as usual protecting groups such as silyl ethers and carbamates. In

a related approach, tin-free intramolecular radical cyclization was performed on substrates, including bromomalonate and unactivated alkenes or alkynes affording five- and six-membered rings.⁴⁶

It has also been demonstrated that ruthenium-based photocatalysis is a powerful tool for direct C–H functionalization of biologically active compounds. Direct α -arylation of bromomalonate using various electron-rich heteroaromatic compounds has been reported.⁴⁷ Optimized reaction conditions allow the direct alkylation of indole **58** with bromomalonate **59** (Scheme 15). The coupling between photogenerated malonyl radical **60** and indol **58** occurs selectively at position 2 to afford compound **61** in 82% yield. The reaction was performed with blue light-emitting diodes.

In such a procedure, the choice of the electron donor involved in the reductive ruthenium catalytic cycle is crucial to avoid undesired side reactions of the malonyl radical **60**. The cross-coupling product is obtained in high yield using 2 equiv of 4-methoxy-*N,N*-diphenylaniline as the electron

Scheme 15 Photocatalytic C–H functionalization of indole.

Scheme 16 Photocatalytic radical cascade reaction.

donor. A broad range of heteroaromatic compounds including furan pyrrole can be alkylated using these optimized reaction conditions. Moreover, the methodology exhibits a broad tolerance for functional groups, which allows the use of unprotected indoles and pyrroles and the presence of sensitive functional groups on the heteroaromatic moiety.

Analogous intermolecular and cascade reactions have also been reported.⁴⁸ Screening of amine electron donors has revealed that triethylamine is the most efficient base used to minimize the amount of the major side product arising from simple reduction of the intermediate malonyl radical. Under optimized reaction conditions, treatment of compound **62** results in the formation of a malonyl radical intermediate **63** that undergoes a double cyclization. The product **64** was obtained in 79% yield as a single diastereoisomer (Scheme 16).

3 NORRISH AND RELATED REACTIONS

Radical intermediates can be easily generated from carbonyl compounds at the excited state. Photoexcitation of simple alkanones leads mainly to a $n\pi^*$ -excited state (either singlet or triplet), which can then produce a biradical intermediate by two main processes.⁴⁹ Homolytic cleavage of the α -bond to the excited carbonyl function is known as

Norrish type I process. Several competitive chemical reactions, mainly decarbonylation and hydrogen abstraction, can then occur from the radical pair. When alkanones have an hydrogen atom in the γ -position, α -cleavage is usually suppressed and γ -hydrogen abstraction by the excited carbonyl function occurs to form a 1,4-biradical. Subsequent cleavage of the biradical to form an enol and an alkene is known as *Norrish type II fragmentation*. The 1,4-biradical can also undergo cyclization by radical combination to produce a cyclic alcohol, a process called *Norrish–Yang cyclization*.

The use of the Norrish reaction in target-oriented synthesis is challenging because of both the competition between this two photochemical primary processes and the selectivity of the biradical intermediate reaction leading to the target molecule. Product distribution obtained from biradical intermediates is variable and is mainly affected by conformational bias. Consequently, bicyclic ketones are useful starting materials to carry out selective Norrish-type reactions. Selected examples of natural product synthesis or analogs that include Norrish reactions as a key step are briefly described below. Unambiguous assignment of the iridoid sesquiterpene specionin structure was made through total synthesis, including a Norrish I reaction as a key step (Scheme 17).⁵⁰ Irradiation at 254 nm in ethanol of compound **65** with a norbornanone framework furnished the crude intermediates **67a** and

Scheme 17 Norrish II reaction as a key step in the total synthesis of *rac*-specionin.

67b resulting from α -cleavage followed by hydrogen abstraction by acyl radical **66**. Acid treatment afforded compound **67c** as the mixture of the four diastereoisomers (at C-1 and C-3) in 64% overall yield. Further transformation of this key intermediate provided *rac*-specionin.

In a synthetic approach toward the sesterterpenoid nitiol, isolated from the biennial medicinal plant *Gentiana nitida* (Gentianaceae), two structurally hybrid 1,22-dihydroxynitienes were synthesized (Scheme 18).⁵¹ The functionalized cyclopentane

“A-ring” of nitiol was synthesized using the conformational bias of [3.3.0]bicyclooctane **68**, constructed via a diastereoselective Pauson–Khand reaction. Norrish I reaction on compound **68** gave access to the isopropyl group of the A-ring. The reaction was carried out on gram scale in methanol using UV light. After α -cleavage and hydrogen abstraction by the isopropyl radical **69** to form the ketene intermediate **70**, addition of methanol results in the production of compound **71** with 82% yield. An analogous Pauson–Khand/Norrish I

Scheme 18 Norrish I reaction as a key step in the A-ring construction of the 1,22-dihydroxynitien nitiol analogs.

Scheme 19 Formal intramolecular asymmetric redox transformation of **72** by organocatalytic intramolecular aldolization/Norrish I fragmentation sequence. Application to the synthesis of (+)-juvabione.

sequence was used by the same group to establish the A–B ring fragment of the fusicoccane family of diterpenes.⁵²

Numerous total synthesis of (+)-juvabione, a natural sesquiterpene exhibiting insect juvenile hormone activity, have been reported. Recently, a strategy based on an organocatalytic intramolecular aldolization/Norrish I fragmentation has been described.⁵³ The highly enantioenriched *endo*-8-hydroxybicyclo[3.3.1]nonan-2-one **73** was obtained by organocatalytic intramolecular aldolization from σ -symmetric 4-(2-formylethyl) cyclohexanone **72**. When compound **73** was irradiated at 300 nm, a Norrish I fragmentation occurred to furnish compound **74** with 60% yield. The overall process can be viewed as a formal intramolecular asymmetric redox transformation of **72** (Scheme 19). Suitable functionalization of compound **73** was done to afford compound **75** with the bicyclo[3.3.1]nonan-2-one framework. The product **76** resulting from the subsequent key Norrish fragmentation was obtained in 66% yield. Five additional steps were then carried out to complete the total synthesis of (+)-juvabione.

γ -Hydrogen abstraction by excited carbonyls followed by coupling of the subsequently formed biradical (Norrish/Yang cyclization) is a powerful and versatile method to produce various carbo- and

hetero-cycles.⁵⁴ The methodology has also been applied to natural product synthesis, as illustrated by the total synthesis of (–)-punctatin A (Scheme 20).⁵⁵ The construction of the completely functionalized trans-fused tertiary cyclobutanol was achieved by irradiation of compound **77** at 254 nm. The diastereoselective coupling of the biradical **78** resulted in the production of compound **79** with the correct stereochemical disposition in a 49% yield. (–)-Punctatin A was then readily obtained from this advanced intermediate.

Intramolecular hydrogen abstraction in a position other than γ , followed by coupling of the formed radical is known as *Yang cyclization*. This process has been extensively studied, especially in the context of macrocycle synthesis.⁵⁶ An interesting application of a long-range hydrogen abstraction by an excited carbonyl function is the selective functionalization of the unactivated positions of the steroid skeleton initially described by Breslow *et al.*^{57,58} When the benzophenone-4-acetic acid ester **80a** derived from 3 α -cholestanol was irradiated, a Δ^{14} -olefin **82a** was obtained as the major product (Scheme 21). Careful mechanistic investigation based on isotopic labeling showed that product **82a** arose from hydrogen abstraction on carbon 14 and that the resulting diradical **81** then transferred

Scheme 20 Norrish/Yang cyclization as key step in the total synthesis of (–)-punctatin.

Scheme 21 Benzophenone remote functionalization of steroids.

the α -hydrogen from C-15 to the benzhydryl radical to complete the process. Two products arising from Yang cyclization at position C-7 **83a** and C-14 **84a** were obtained in a lower yield as single benzhydryl epimers (17 and 4% yield). As expected, the

selectivity of the overall process is strongly dependent on conformational constraints, as illustrated by experiments with more flexible compounds. For example, when a benzophenone-4-propionic acid ester analog **80b** was used, the Δ 14-olefin **82b** was

Scheme 22 Photochemically induced extrusion of carbon monoxide from cyclic ketones in crystal leading to stereoselective radical cyclization.

the minor product and **83b** and **84b** were the major products, both obtained as an equimolar benzhydryl epimeric mixture, arose from Yang cyclization at C-7 and C-14 (C-7 55% and C-14 19% global yield). The benzophenone remote functionalization reaction is a powerful method for the functionalization of steroids that have been recently used in the synthesis of xestobergsterol A⁵⁹ and the shark repellent, pavoninin-4.⁶⁰

Photochemical conditions for the extrusion of small molecules are widely applied. Frequently, radical intermediates are generated. Such a typical example is the extrusion of carbon monoxide from cyclic ketones, which can be carried out by irradiation of substrate crystals. This transformation may also be considered as a double Norrish I reaction. A crystal suspension of the cyclohexanone derivative **85a** possessing *S* configuration at position 5 was irradiated with UV light (Scheme 22).⁶¹ Compound **85a** undergoes double α -cleavage leading to the biradical **86**. Stereospecific radical combination leads to the cyclopentane derivative **87**. The stereoselectivity was controlled by the rigid environment of the crystal. When carried out in solution, a mixture of diastereoisomers was isolated from the photochemical transformation. It must be further pointed out that the transformation allows to create two adjacent quaternary centers. In two additional steps, the target (+)-cuparenone is obtained. This enantiomer

was isolated from the wood of the mayur pankhi (*Thuja orientalis*). The corresponding transformation of a crystal suspension of the diastereomeric cyclohexanone derivative **85b** possessing *R* configuration in the position 5 was conducted with the same efficiency. It was used for the synthesis of (–)-cuparenone. This enantiomer was isolated from the liverwort *Mannia fragrans*. The same synthesis strategy was applied to the synthesis of herbertenolide.⁶² A similar photochemical transformation of a crystal suspension was carried out on the scale of 10 g.⁶³

The decarbonylation is a reversible process. For example, under CO pressure, alkyl radicals may generate acyl radicals.⁶⁴ This reaction was also applied to organic synthesis.

4 REMOTE FUNCTIONALIZATION WITH HETEROATOM-CENTERED RADICAL INTERMEDIATES

4.1 Intramolecular Remote Functionalization with Oxygen-Centered Radicals

Photochemical transformations of nitrite esters have frequently been applied to the synthesis of biological active compounds of the steroid or triterpene

Scheme 23 Radical remote functionalization with nitrite esters. Application to the synthesis of oleanolic acid derivatives.

Scheme 24 Radical remote functionalization with nitrite esters. Application to the synthesis of alkaloids.

sapogenine families.^{65,66} The oleanolic acid derivative **88** was successfully transformed into **89** on a 20-g scale (Scheme 23).⁶⁷ The reaction starts with a homolytic cleavage of the N–O bond of the nitrite ester function (**90**). The resulting alkoxy radical selectively abstracts a hydrogen atom from position 27 (**91**). Trapping that radical with NO (**92**) and tautomerization leads to the final product. This transformation belongs to strategies involving remote intramolecular functionalization.^{68,69} As in many cases of radical reactions, an otherwise particular challenging selective C–H bond activation of an alkane takes place. Further transformations of

89 afford compound **93**, which may be a synthesis intermediate for the preparation of myriceric acid A. This acid is a potent and specific endothelin A receptor antagonist.

The reaction was also applied to the synthesis of alkaloids. Thus, irradiation of the nitrite ester **94** afforded the oxime **95** in good yield and complete regioselectivity (Scheme 24).⁷⁰ This reaction is useful for the synthesis of a family of tropane alkaloids derived from 3 α ,6 β -dihydroxy-*N*-methyltropane **96**.⁷¹ The photochemical transformation of nitrite ester was also applied to the synthesis of the quinuclidine part of chinchona alkaloids. Thus,

Scheme 25 Radical remote functionalization with diacetoxyiodobenzene in combination with iodine. Application to the multistep synthesis of (+)-bistramide.

compound **97** yielded stereo and regioselectively the oxime **98** (Scheme 24).⁷² Other methods of remote oxidations involving heavy metal ions were unsuccessful, perhaps due to complexation properties of the quinuclidine derivatives. After hydrolysis, ketone **99** is obtained, which may easily be functionalized in one of the α -positions to the carbonyl function. This strategy significantly differs from the classical way involving 3,4-substituted piperidine intermediates⁷³ and represents an alternative method to establish relative stereochemistry in quinuclidines.

A number of such transformations have efficiently been carried out using diacetoxyiodobenzene in combination with iodine^{74–76} and applications to total synthesis of complex biological products such as eposydictymene⁷⁷ and candicanoside A⁷⁸ or complex symmetrical hydrocarbon compounds⁷⁹ have been reported. The dihydropyran derivative **100** was irradiated with visible light in the presence of diacetoxyiodobenzene and iodine (Scheme 25).⁸⁰ Intermediately, the oxygen-centered radical **101** is generated. Intramolecular hydrogen

abstraction leads to the more stable radical **102** on the dihydropyran moiety. Further steps afford the mixture of spiroacetals **103** and **104**. The final product **105** was obtained by *in situ* reduction with LiAlH_4 followed by dehalogenation of the minor product **104** with tributyltinhydride. Further transformations lead to (+)-bistramide C. Bistramides have been isolated from marine ascidian *Lissoclinum bistratum*. These compounds possess a variety of biological properties such as sodium channel blockage or unique protein kinase C δ activation. The present synthesis was carried out in order to confirm the configuration of (+)-bistramide C.

In a similar way, the tricyclic compound **106** obtained from **107** by a cyanhydrin reaction was transformed into the acetal **108** (Scheme 26).⁸¹ The yield of this regio-specific radical reaction was almost quantitative. Further transformations led to (–)-paeoniflorin. This monoterpene glucoside was isolated from *Paeonia albiflora* Pallas. This plant is used in traditional oriental medicine as an analgesic, an antispasmodic, an astringent, or a sedative.

Scheme 26 Radical remote functionalization with diacetoxyiodobenzene in combination with iodine. Application to the multistep synthesis of (–)-paeoniflorin.

4.2 Intramolecular Remote Functionalization with Nitrogen-Centered Radicals

The Hofmann–Löffler–Freitag reaction is related to this reaction and many transformations of this type have been carried out under photochemical conditions. In this case, nitrogen-centered radicals are generated as key intermediates. Consequently, many applications have been reported in the field of alkaloid synthesis. UV irradiation of the *in situ*-generated chloroperhydro quinuclidine derivative **109** afforded dihydrodeoxyepiallocernuine (Scheme 27).⁸² Protonated radical intermediates **110** and **111** have been discussed.

For detailed investigations on the mechanism of the Hofmann–Löffler–Freitag reaction, see Refs 83–85.

Diacetoxyiodobenzene and iodine were also used to generate N-centered radicals in the Hofmann–Löffler–Freitag reaction. When the steroid derivative **112** possessing a nitrosamine function is irradiated under these conditions, a pyrrolidine ring is formed (**113**) (Scheme 28).⁸⁶ The high yield of this transformation is explained by the proximity and the parallel orientation of the methyl group and the nitrosamine function in B-ring of the steroid system. The same reaction was carried out with a variety of polycyclic nitrosamines and cyanamides.⁸⁷

Scheme 27 Radical remote functionalization using the photochemical Hofmann–Löffler–Freitag reaction.

Scheme 28 Radical remote functionalization with diacetoxyiodobenzene in combination with iodine. Application to the synthesis of a steroid-alkaloid.

5 TRANSFORMATIONS WITH SULFUR-CONTAINING FUNCTIONAL GROUPS

Sulfur-containing derivatives play a central role in radical chemistry. In many studies involving thiocarbonyl derivatives, radical intermediates are released by removal of the thiocarbonyl moiety (see **Xanthates and Related Derivatives as Radical Precursors** and **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**). In most cases, this step occurs by addition of another radical species at the sulfur atom of the C=S bond. Several of these functions can also be activated by photochemical excitation as in the case of carbamoyl diethyldithiocarbamate **114** (Scheme 29).⁸⁸ The irradiation with visible light of this compound leads to the formation of the carbamoyl radical **115**. It undergoes 5-*exo*-trig cyclization and the resulting secondary alkyl radical **116** reacts with substrate **114** affording the final product **117**.⁸⁹ In this step, a thiocarbamate function is transferred and a carbamoyl radical **115** is generated. The cycle of the radical chain reaction is thus completed. Lactam **117** constitutes the aliphatic

bicyclic moiety of the alkaloid (–)-aphanophine isolated from freshwater green alga *Aphanizomenon flos-aquae*. Such compounds may possess interesting pharmaceutical properties due to structural similarities to non-natural analgesics such as morphine or eptazocine. In order to obtain a further synthetic intermediate, an aromatic ring was built (**118**). Previous literature reports the transformation of this compound into (–)-aphanophine.

In a similar way, acyl xanthates have been photochemically activated with visible light and the C–S bond was cleaved.⁹⁰ Intermolecular addition to polyunsaturated compounds led to polycyclic final compounds of triquinane type.

On irradiation, Barton esters^{91,92} generate radical intermediates in a convenient way.^{93,94} Thus, irradiation of **119** obtained directly from the carboxylic acid **120** leads to the cleavage of the N–O bond (**121**) (Scheme 30).⁹⁵ After release of CO₂, the carbon-centered radical **122** is formed. In the presence of a hydrogen donor such as *t*-butylmercaptane, this intermediate is trapped and the final product **123** is obtained. The reaction has been tested in the total synthesis of platensimycin, which was isolated from a strain of *Streptomyces platensis*. It possesses antibiotic properties.

Scheme 29 Radical cyclization induced by photochemical cleavage of carbamoyl diethyldithiocarbamate **114** and its application to alkaloid synthesis.

Scheme 30 Photochemical cleavage of a Barton ester leading to decarboxylation. Application to the synthesis of platensimycin.

Such carbon-centered radicals obtained from Barton esters are also trapped with disulfides. Irradiation of the fluorinated steroid **124** generates the radical **125**, which is trapped by disulfide **126** (Scheme 31).⁹⁶ Two stereoisomers **127a** and **127b** of the final product were isolated. Under basic conditions, a big part of the isomer **127a** can be transformed into **127b**. A 1:9 mixture is thus obtained. Thus, a large variety of glucocorticoid agonists have been synthesized and tested mainly in the context of their anti-inflammatory properties.

Carbon-centered radicals generated by release of CO_2 and pyridine-2-thiyl radicals can also be trapped with alkenes. The Barton ester **128** was directly produced from the corresponding acid. In this case, the pyrrole derivative **129** was transformed with the acrylamide **130** (Scheme 32).⁹⁷ As in many cases, the photochemical transformation

of this compound was carried out *in situ*. CO_2 is released and the two radical species **131** and **132** are formed. The nucleophilic radical easily adds to electron-deficient double bonds such as acrylamides (**133**). The final product **134** is obtained by radical combination of the oxoallyl **133** and the pyridine-2-thiyl radical **132**. Stereoisomers possessing different configurations at position 4 are formed in almost equal amounts. The 4-*S* isomers have been transformed into (+)-indolizidine 167B. Such alkaloids are isolated from the skin of neotropical frogs. The compounds possess a variety of biological activities.

Trapping carbon-centered radicals resulting from photochemical cleavage of Barton esters and addition to maleic anhydride was applied to the synthesis of novel inhibitors of Cdc25 dual

Scheme 31 Photochemical cleavage of a Barton ester leading to decarboxylation. Radical trapping with a disulfide.

Scheme 32 Photochemical cleavage of a Barton ester leading to decarboxylation. Application to the synthesis of an indolizidine alkaloid.

Scheme 33 Generation of alkoxy radicals by irradiation of a thiazole-2[3H]-thione derivative.

specificity phosphatases⁹⁸ and for peptide synthesis on solid phase.⁹⁹

In the same way, corresponding *N*-alkoxy pyridinethiones have been used as precursors of alkoxy radicals.¹⁰⁰ Corresponding *N*-alkoxy-4-methylthiazole-2[3H]-thione revealed to be more efficient.¹⁰¹ Thus compound **135** was irradiated in the presence of bromotrichloromethane, which leads to the formation of the alkoxy radical **136** along with the thiazole derivative **137** (Scheme 33).¹⁰² Intramolecular addition followed by bromine abstraction affords the final products **138a** and **138b**. After chromatographic separation, they were transformed into (–)-muscarine and (+)-*allo*-muscarine. Muscarine and some of its stereoisomers have been isolated from different fungal species. Owing to its action on the parasympathetic nervous system, such compounds are of pharmaceutical interest.

6 RADICAL REACTIONS INDUCED BY PHOTOCHEMICAL CLEAVAGE OF TIN REAGENTS

Trimethylstannyl radicals are frequently used to start radical reactions. These intermediates are produced, for instance, by photochemically supported cleavage of the Sn–Sn bond in hexamethylditin. They are capable of halogen abstraction as shown in Scheme 34.¹⁰³ Thus, the vinyl radical **140** is obtained from **139**. Addition of phenylisocyanide **141**

leads to the iminyl radical **142**. 5-*endo*-dig Cyclization (**143**) followed by a 6-*exo*-trig builds up the polycyclic scaffold of camptothecin. This transformation can be performed with visible light.¹⁰⁴ Replacement of hexamethylditin by hexamethyl disilane is possible. However, the yields of this transformation are lower. Camptothecin is a natural product, which originates from traditional Chinese medicine. It possesses cytotoxic and antiviral properties. Several structural analogs have been obtained in the same way. Similar intramolecular reactions have been carried out using the same method.¹⁰⁵

This type of reaction has also been applied in carbohydrate chemistry. Two examples are depicted in Scheme 35. Glucosyl radical intermediates were generated from glucosyl bromide **144**.¹⁰⁶ They are easily added to the sulfonyl oxime **145**, which leads to the C-glucoside **146**. Frequently, tin hydrides such as tributyltinhydride are used for such transformations (see **Tin Hydrides and Functional Group Transformations**). In the present case, under such conditions, the yields are lower and considerable amounts of reduction products are also formed. Under the optimized reaction conditions, however, the reaction was successfully carried out with a variety of carbohydrate halides and in different positions of the pyranosyl ring. The same reaction was applied to the synthesis of spironucleosides.¹⁰⁷ Allyltin compounds have been successfully used in the same context. Thus, the CF₂Cl-substituted 6-deoxy-L-galactopyranoside **147** was selectively transformed into the corresponding

Scheme 34 Radical tandem reactions induced by photochemical cleavage of hexamethylditin. Synthesis of camptothecin.

Scheme 35 Photochemically induced radical reactions applied to the synthesis of C-glycosides.

difluorobutenyl derivative **148**.¹⁰⁸ Under these photochemical conditions, no further radical initiator such as AIBN is necessary. The CF₂ group imitates the oxygen atom in normal glycosyl derivative. When compared to corresponding glycosides, such difluoromethylene compounds are more stable.

7 CONCLUSIONS

Photochemical reactions considerably enrich radical chemistry methodology. In many cases, such reactions are carried out under milder conditions and complex multifunctional substrates can selectively be transformed. In photochemical reactions (e.g., Norrish reactions), radical intermediates are often generated by homolytic cleavage. This elementary

step demands high transition energy. Radical intermediates can also be generated in a less energy demanding two-step process involving photochemical electron transfer and the formation of a radical ion pair as additional intermediates. In many cases, reagents such as AIBN or peroxides used as initiator for a chain reaction at the ground state are not needed. Thus, side reactions and waste formation are diminished. Consequently, numerous applications in organic synthesis, particularly in the field of biologically active compounds (natural products and pharmaceuticals), have been reported.

Concerning photochemical transformations, it is particularly challenging to use visible instead of UV light. Recent results in the field of photoinduced electron transfer reactions are particularly encouraging and thus open numerous perspectives for

applications in organic synthesis. The mild reaction conditions and the high selectivity of such transformations are particularly attractive in the context of sustainable (green) chemistry.
